INTRODUCTION

Many of today's global problems arise from the availability and use of natural resources, caused by growing population and changes in lifestyle. The Ministry of New and Renewable Energy of India (Energy Access, 2012) states that India has the world's 5^{th} largest generation capacity and it is the 6th largest energy consumer accounting for 3.4% of global energy consumption.

In Europe the construction sector is in a change process, especially concerning the energy aspects. Buildings effect 40 % of total EU energy consumption and generate 36 % of greenhouse gases. To decarbonize the European economy reducing CO_2 emissions by at least 80 % and energy consumption by as much as 50 % by 2050 is necessary.

According to the EU Building Directive, European Parliament (2010), all member states have to ensure that by December 2020 all new buildings will be "Nearly Zero Energy Buildings". The various green successful schemes and initiatives undertaken by Austria will be discussed and understood. Austria is also a forerunner in eco building and passive houses.

INTENT AND OBJECTIVES

Need for sustainable habitats

Today, India is the second fastest growing economy in the world. In India, construction is the second largest economic activity after agriculture.

National Resources Defence Council and the Administrative Staff College of India have proposed a report on Strengthening the Indian Real Estate Market Through Codes and Incentives (2014) which clearly states: If all the states across India adopted the Energy Conservation Building Code (ECBC) and developers participated in strong programs for rating commercial buildings, an estimated 3,453 TWh of cumulative electricity could be saved by 2030, the equivalent of powering as many as 358 million Indian homes annually between 2014 and 2030 based on the current annual consumption level for electrified households. Additionally, 1,184 million tons of CO_2 emissions could be avoided by 2030. This underlines the need for sustainable habitats in India by creating a mass awareness and implementing stricter building standards.

Need for new policies and measures

According to IEA statistics report (2011), the electricity consumption in India has nearly doubled from 407.48 TWh in 2000 to 835.40 TWh in 2011 and the CO_2 emissions have risen drastically from 972.13 Mt of CO_2 to 1745.06 Mt of CO_2. From these figures we can infer the higher are the electricity consumption, higher is the CO_2 emissions. Though India has a number of policy initiatives to mainstream energy efficiency and green buildings as control and regulatory instruments, including appliance standards, mandatory labelling and certification, energy efficiency obligations, and utility DSM (Demand Side Management) programs; economic and market-based instruments; fiscal instruments and incentives; support, information and voluntary action, there is definitely a strong need for better solutions to create a wider impact to achieve low carbon economy in the coming years.

Integrated Design

Integrated Design is advisable in managing the complex issues arising from planning buildings with high environmental and social ambitions. Key issues are collaboration in multi-disciplinary teams,

Author A is a master student at FH Joanneum, Kapfenberg, Author B is a Senior Professor at the Master Program at FH Joanneum, Graz ,Austria, Author C is a Managing partner of 17&4 Consulting Ltd., Vienna, Austria, Author D is Chief Executive and Director of CSAPL, Salem, India

discussion and evaluation of multiple design concepts as well as clear goal setting and systematic monitoring. In the early design phases, the opportunities to positively influence building performance are great, while cost and disruptions associated with design changes are comparatively small.

The Integrated Design Approach will result in better energy performance, reduced environmental problems, optimized indoor climate, lower running costs, reduction of risks and construction defects, user acceptance and higher process quality concerning timelines, construction cost, quality of work delivered.

EXISTING POLICIES AND MEASURES IN EUROPE

Case study Austria

Austria is a European country with a comparable high share of Nearly Zero Energy Buildings and was one of the forerunners in eco building in the last twenty years. This development was enabled by a sample of instruments:

Building Codes: The building codes are adapted step by step towards the "Nearly Zero Energy Standard" to implement the European Building Directive on national level. The National Plan OIB, (2011) specifies the limits for heat energy demand, primary energy and CO_2 for new buildings and also in case of renovation.

Subsidies: In Austria subsidies for building or renovation are available if specified building standards e.g. heat energy demand, are documented in the obligatory energy passport. In general the energy performance must be better than the building code requirement. The City of Vienna evaluates social housing building projects by an interdisciplinary jury and launches competitions for sustainable building. The subsidy for a solar thermal plant with a solar fraction of the heating energy demand (for heating and hot water) of at least 30 percent is 25 percent of the eligible investment costs.

Government initiative for public buildings: For public buildings, the governments of the provinces take the responsibility as a trend-setter in green public procurement; specific criteria were developed by consultants in tight cooperation with the administration. The Planners Guideline Planungsleitfaden Vorarlberg (Fechner, Haas, 2010) is a crucial tool for the implementation to be practiced.

National Programs: Programs are the third pillar beside the legal and economic instruments for climate policy. The Austrian Program on Technologies for Sustainable Development "Building of Tomorrow" initiated innovation in sustainable buildings like Passive House demonstration projects, development of building concepts and components, social studies. The Program "Factory of Tomorrow" addresses the trade and industry as well as service enterprises to focus on zero-waste and zero-emission technologies and methods of production, increased use of renewable raw materials for materials and products, development of new partnerships and co-operations as well as in-house models for further training and participation of employees in order to achieve these objectives

Klimaaktiv is embedded in the Austrian federal climate strategy, consisting of a bundle of measures of regulation, taxes, and subsidies. Klimaaktiv has gathered all voluntary and supportive measures under one umbrella in the four thematic clusters construction, energy efficiency, mobility and renewable energy. The climate protection program goes into partnerships to realize climate friendly building.

The core objectives of klimaaktiv are:

1. Training for professionals: the European BUILD UP Skills initiative launched national stakeholder platforms to develop roadmaps for vocational training concepts in the construction sector. By this the needed skills to realize the Building Directive shall be built up. klimaaktiv supports and provides qualification and coordinates training and vocational education in various fields.

Author A is a master student at FH Joanneum, Kapfenberg, Author B is a Senior Professor at the Master Program at FH Joanneum, Graz ,Austria, Author C is a Managing partner of 17&4 Consulting Ltd., Vienna, Austria, Author D is Chief Executive and Director of CSAPL, Salem, India

2. Setting standards and safeguarding quality by introducing quality standards for products and services and by establishing quality management systems, e.g. for biomass district heating systems or for buildings. This is important, because young and booming markets often cannot provide sufficient quality.

3.Providing information and advice, raising awareness; klimaaktiv mainly focuses on offering consulting to companies interested in making their production processes energy efficient, or renovating their facilities, or introducing mobility management, or changing over to energy efficient appliances and IT systems. klimaaktiv provides support for consultants by equipping them with new tools, by benchmarking energy efficiency and by offering further training on specific issues.

4. Activating and networking partners; successful climate protection depends on the commitment of existing initiatives and networks as well as on that of the business and the public sector. klimaaktiv aims at bringing these players together and at creating a powerful network for climate protection.

Figure 1: This Logo is used by partners of the initiative to express the engagement in climate protection

Building standards: In Austria several certification schemes are in use to label buildings:

* **EU Green Building:** compared to other systems this standard is not covering many aspects of sustainable building

* **klimaaktiv building standards:** for new and renovated buildings, free available on www.klimaaktiv.at , with reference to passive house standards

* **OGNB**, Austrian Sustainable Building Council (including klimaaktiv criteria)

* **BREEAM,** Building Research Establishment Environmental Assessment Methodology

* **ÖGNI,** Austrian Association for Sustainable Real Estate Management (ÖGNI), Germany's DGNB.

The use of building standards is required for public buildings or for funding occasionally

Consultancy: Energy advising is very common in Austria to raise the awareness and to help to make best use of subsidies. Consultants are organized in networks by the provinces. The service is offered free or to a low price, sometimes it is part of the subsidy.

Tools for planners: Sustainable Buildings require new competences in management of integrated planning processes. Starting with the establishment of clear project goals and quality management and ending with final inspection protocols, user information and maintenance. As an example, the series "Quality line" for the optimized integration of solar heat, heat pumps, HVAC, is provided by the klimaaktiv initiative, (Fechner, J., 2012) Qualitaetslinien Haustechnik.

Table 1. Quality Line in the Construction Process

Step	Tool of Quality Line
1. Basic Decisions	Information for Purchaser, Checklist
2. Call for Tender/Cost Estimate	Specifications for Tender
3. Selection of Tender, Contract	Criteria
4. Quality control	Inspection Protocols

Author A is a master student at FH Joanneum, Kapfenberg, Author B is a Senior Professor at the Master Program at FH Joanneum, Graz ,Austria, Author C is a Managing partner of 17&4 Consulting Ltd., Vienna, Austria, Author D is Chief Executive and Director of CSAPL, Salem, India

For the selection of energy efficient electric appliances a consumer friendly database is run by klimaaktiv, presented on www.topprodukte.at. Professionals find here the most efficient pumps, boilers and many other components, end-user are most interested in energy demand, investment and running costs of household appliances.

WHICH OF THE PRESENTED STRATEGIES AND MEASURES CAN BE REGARDED AS USEFUL FOR SUSTAINABLE BUILDINGS?

- Sustainable building must be defined in the context of the country, its climate, culture and society. Sustainable concepts have to unite ecological, social and economic requirement, they are always the result of discussion, valuation and negotiation. Exchange of experience and learning from each other is urgent to solve problems on global level.
- Certification schemes provide information and criteria for sustainable buildings. Depending on the origin of the scheme the criteria are based on the understanding of the creator and his system.
- A Sustainable Building Strategy is the basis for a coordinated and effective development of the building sector. The EU Building Directive is an efficient policy strategy, but it covers only the use of energy. Other aspects of sustainability need to be met.
- National programs for sustainable buildings are triggering innovation and good practice support the market transformation. As soon as sustainable solutions are available, legal and economic measures (e.g. subsidy schemes) are necessary to implement such a strategy. Quality management is crucial, it is the responsibility of the investor and user to define sustainable quality and proof, as the legal requirements and the administration only regulate some aspects.
- National initiatives like klimaaktiv are bundling measures to reach grassroots level. If the government introduces such a scheme, it is available nationwide for free.

Seven steps can be identified as core elements referring to existing practice in Europe and India, the authors propose to implement and coordinate these measures within a national initiative:

1. Analysis of building practice incl. energy performance, poor quality and damages (first part of SWOT analysis). In cooperation with Universities such research can be a field of learning and many researchers can be involved.
2. An innovation program for sustainable building produces the options for the future, involving Universities and the building industry.
3. Building standards for all relevant kind of buildings incl. domestic buildings (e.g. klimaaktiv building standards in Austria or in Switzerland MINERGIE)
4. Analysis of stakeholders and actors (to learn about their need for capacity building) and definition of learning targets.
5. Development of a vocational training scheme for sustainable building incl. certification (e.g. ISO 17024). Trainings can be offered by educational institutions, based on contracts.
6. Networking and partnership. Persons who absolved special trainings are invited to join the network of sustainable building professionals
7. Evaluation of trainings, refining trainings.

An evaluation of Austrian tools towards adaptation to India could be made; Energy Consulting for investors and for users could be mentioned; universities could engage in a targeted exchange of academic staff and students to learn from each other.

Author A is a master student at FH Joanneum, Kapfenberg, Author B is a Senior Professor at the Master Program at FH Joanneum, Graz ,Austria, Author C is a Managing partner of 17&4 Consulting Ltd., Vienna, Austria, Author D is Chief Executive and Director of CSAPL, Salem, India

OUTCOMES: RECOMMENDATIONS FOR SUSTAINABLE HABITATS IN INDIA

A program "Sustainable Building for India", implementing the discussed strategies and measures can make sustainable habitats a greater success in India.

- Awareness raising should start with presentation of good practice, e.g. an award for sustainable buildings(http://www.klimaaktiv.at/bauensanieren/staatspreis.htmlor http://iet.jrc.ec.europa.eu/energyefficiency/greenbuilding) .
- Besides (more or less expensive) certification schemes additional incentives should be developed. The above mentioned strategies and measures can be used but must be adapted, as India has different climatic conditions; the architecture of the building varies from region to region.
- The Government of India can encourage industries; especially SME's to come up with new green materials at affordable cost so that the end user can implement the green idea into reality.
- In India, Excise Duty is imposed on every product that is manufactured in factories. The Government should intervene by reducing the service tax and other taxes imposed on products manufactured by Certified Green Factories to encourage green practices.
- The Government of India can introduce subsidy schemes either nationwide or state wide for green building practices to encourage active participation by the public.
- To encourage Sustainable Building and also to increase the share of renewable energy, an increase of the budgetary allocation by the Government of India is necessary.
- The Government of India can enforce a strict regulation all over the country to increase the share of renewables from the existing 1% to 10% like the EU Building Directive.
- Construction workers should be trained to understand the various green building practices throughout the construction period. Before the Project work has begun, the contract should have a mandatory agreement that trainings in green building practices have to be undertaken by supervisors, clients at different stages of the project to understand the purpose.
- When constructing a new building, license from EIA has to be obtained. Renewable practices must be stressed and included in the license procedure
- When the customer approaches bank for loans for green residential or commercial projects usually environmental approvals are requested for the financial closure but no such requirements regarding energy approvals.

TOOLBOX FOR INTEGRATED DESIGN FROM AUSTRIAN INITIATIVE ' KLIMAAKTIV'

Klimaaktiv provides tools for effective Integrated Design for Sustainable Buildings in Austria. These tools are available for free and have great potential to be used as powerful tools for Indian habitats. Guidelines for optimized integration of photovoltaic, solar heat, HVAC and electric appliances, air quality are given. Klimaaktiv would also help in the transfer of knowledge for India to make integrated design reachable to all. The various Tools are listed below.

1. Photovoltaic calculator is an efficient tool (xls tool) for the rapid assessment of efficiency of photovoltaic systems for new construction and renovation buildings. It is available in the web link (http://www.klimaaktiv.at/tools/erneuerbare/pv_rechner.html)

Author A is a master student at FH Joanneum, Kapfenberg, Author B is a Senior Professor at the Master Program at FH Joanneum, Graz ,Austria, Author C is a Managing partner of 17&4 Consulting Ltd., Vienna, Austria, Author D is Chief Executive and Director of CSAPL, Salem, India

2. Solar heat: Guidelines for counselling, call for tender, acceptance protocol are given for systems for residential buildings for heating water, with or without integration in the heating system. (http://www.klimaaktiv.at/publikationen/bauen-sanieren/qualitaetslinien/solarwaerme.html)
3. HVAC:
   Guideline for counselling, call for tender, acceptance protocol (http://www.klimaaktiv.at/publikationen/bauen-sanieren/qualitaetslinien/komfortlueftung.html)
4. Heat Pumps :
   Guidelines for counselling, call for tender, acceptance protocol buildings for compact devices (http://www.klimaaktiv.at/publikationen/bauensanieren/qualitaetslinien/komfortlueftung.html) and to find the right heat pump heating , JAZcalc derives the seasonal performance factor under standard conditions for a quality geothermal community
   (http://www.klimaaktiv.at/tools/erneuerbare/JAZcalc.html)
5. Indoor Air Quality : criteria in klimaaktiv
   - HVAC (http://www.baubook.at/kahkp/?URL_R=http%3A%2F%2Fwww.baubook.at%2Fm%2FPHP%2FKat.php%3FSKK%3D1761.13213.13214.13255.13257.13243%26SW%3D8%26ST%3D12&SW=8)
   - Selection of building products (low emission) (www.baubook.at)
   - Qualitycontrol(http://www.baubook.at/m/PHP/Kat.php?SKK=1761.13213.13214.13255.13257.13245&SW=8&ST=12)
6. Environment data: baubook.at also provides data for Global Warming Potential, Acidification Potential and Primary Energy (grey energy)
   (http://www.baubook.at/m/PHP/Baum2.php?ST=44&SW=8&auto_right_frame=y)
7. In order to make the quality of a building measurable and comparable, the climate-active building standard was developed.
   (http://www.klimaaktiv.at/bauen-sanieren/gebaeudedeklaration.html) and in English (http://www.klimaaktiv.at/english/buildings/Buildings.html)
8. There are various Labels: e.g. solar key mark for solar thermal (http://www.estif.org/solarkeymarknew/) or EHPA for heat pumps (http://www.ehpa.org/). It is easy to handle quality labelled products.

CONCLUSION

Even though the climate is different in Austria and India, many principles and in the meantime also many products are basically the same all over the world. Useful elements of the presented toolbox can be adapted to promote sustainable engineering and building.

The leading engineering schools can initiate innovation for sustainable building, facilitating hands-on “real life” education and continuous exchange with industry on new technologies, materials and process design. Such an educational model focusses on the student’s role as active “innovation broker” between his employing company and the teaching and research staff at the university. Austria can contribute and bring in examples for innovative and successful didactic and organizational elements and their actual benefit for regional enterprises.

ABSTRACT

Full scale buildings sometimes are too big to be fully monitored and, moreover, if occupancy are inside, they can fail some measurements. FINAOSTA (Finanziaria Regionale della Valle d'Aosta/ Regional Holding Company of the Aosta Valley) is a research activity conducted by University of Florence on two buildings – one school and one office building- located in North Italy, Aosta. Buildings have different age, different exposition, different material construction. Aim of the research is to propose an appropriate methodology to monitor thermal plant and to investigate on technical solutions for reducing energy consumptions in both buildings. Two different plant system solutions are identified and buildings are monitored through an electronic system regulated from an internet platform; data collected are used to evaluate energy saving and indoor comfort due to both technical solutions. Due to the high volume of the building, a decision has been made on portions to be monitored and compared: results are used as input to simulate the full scale buildings. The paper will evidence difficulties in defining zones to be monitored and obstacles due to the inappropriate intervention of occupants on the instrumentation.

INTRODUCTION

This research focused on problems in monitoring and simulating full scale building with high volume as school or offices, and to compare different technical solutions adopted for the heating and cooling plants.

Very often monitoring results can be unreliable and the parameters to be monitored are difficult to predict or to model depending on the accuracy of the simulating model level. A common practice is to use energy simulation tools to verify monitoring results: in this research activity energy simulation has been used to extend investigation on monitored parameters and energy requirements due to application of different technical solutions on full scale building, so the main difficulty was the right scale model in ESP-r [1] (the energy tool used for energy dynamic simulations) to achieve the objectives of research. In addition, during all the research stages, many problems was related to uncertainty of results due to human factor for two reasons: In monitoring activities, users actions interfering with the right functioning of monitoring equipments, making difficult to interpret results and to compare monitoring data in different rooms. In energy simulation activities it was impossible to translate users behavior and to describe active control plants by occupants through operational control law with a dynamic simulation tools. This type of problem suggests the necessity to develop new strategies and methodologies to analyse the state-of -art in full scale dynamic monitoring and energy simulation.

OBJECTIVES

The main objective of FINAOSTA research activity is to verify the energy saving and the convenience due to one of the technological solutions for plants compared to the others. As explained, an utility in using building energy simulation is to simulate the impact of each technological solution for plants on full scale building even if, in reality, technical solutions has been applied only on portions of buildings. In this work, the investigations carried out on the office building and the school started to verify: the energy required for each building considering the application of the heating and cooling system control devices and the energy consumption; the indoor comfort of occupants in workplaces.

Therefore starting from a known of the building total consumptions and using monitoring results to simulate full scale building, it is possible to define the reasons of occupants discomfort and to evaluate the buildings energy requirements considering internal gains during the simulation period. Finally, comparing different plant system solutions introduced into the buildings during the monitoring period it estimated the economic costs during plants operation periods. It was possible to propose and to evaluate the impact of technological solutions adopted for the plants and for the building skin, and how these aspects can reduce the energy consumption and the comfort level of occupants.

DESCRIPTION OF BUILDINGS

The Department for Productive Activities of Aosta (Fig.1) was built in 1939 and actually consists of two building blocks: the earliest building with a mansory structure, brick external wall 70 cm thick and concretebrick floors, thermal plant has a heating functioning only with radiators; a new block to the West, built around 1980-1990 with a reinforced concrete structure, brick external wall 35 cm thick at the ground floor and a double glazing facade at the first and second floor; thermal plant with fan coil has a heating/cooling functioning [2] .

Fig ... Aosta.(a) earlie ... n
West exp

The Manzetti School (Fig.2)was built in 1958 and consists of four storey in which there are classrooms, laboratories, and administration offices and a basement for deposits and archives. The building has a concrete structure with brick external walls 50.00 cm thick with a natural stone cladding on the fronts along public road and plaster on the fronts along intern court, concrete-brick floors, floors in brick and pitched roof with ceiling tile and the concrete slab finish in terracotta tiles. The school is served by a thermal plant for the winter heating only with radiators [3].

THE ENERGY ANALYSIS PROGRAM

The purpose of energy analysis is the identification of technological and innovative/non-invasive solutions to optimize the heating/cooling plant systems and the comfort indoor in workplaces.

The operational phases preliminary to monitoring activity:

1. Identifying groups of representative rooms in both buildings for the monitoring. Three groups were identified, differing for exposure, construction elements for facades, thermo-hygrometric conditions, and type of plants. Each

group consists in three rooms: Room 1; Room 2 and Room 3;

2. Monitoring of thermo-hygrometric parameters into the rooms and analysing technological systems and construction typology of facades, windows and doors transmittance, heat capacity, thermal inertia, etc.

This first analysis performs a first setting of the REMOTE MANAGEMENT SYSTEM (monitoring, control and regulation) as an innovative technology solution.

Fig. 2. Manzetti School building. (a) South front with natural stone cladding; (b) East front with plaster cladding.

Methodology and parameters of the Energy analysis

For each building it has been chosen a "thermal zone monitoring", consisting of groups of three rooms with the same use and exposure. The groups has been studied, investigated and monitored by installing tiny-tags for the measurement of dry bulb Temperature (dbT) and relative Humidity (RH). The accuracy of instruments is ±0.5°C at 25°C for dbT and ±3.0% at 25°C for RH.

These parameters have been recorded and compared to the graphs concerning the ambient temperature and humidity measured by outdoor tiny-tags. This allowed to analyse the dynamic behaviour of buildings related to the external climatic conditions and to control the heating/cooling system operation.

The following indoor parameters have been monitored for each room:

- dry bulb temperature in the volume occupied by people (about 1.60 m above the floor);
- dry bulb temperature near the ceiling (about 20 cm below the ceiling);
- relative humidity in the volume occupied by people (about 1.60 m above the floor);
- thermal energy provided by each radiator/fan-coil.

The outdoor parameters monitored are:

- outdoor dry bulb temperature;
- outdoor relative humidity.

Indoor temperature and humidity in the room air volume represent two parameters to verify and optimize indoor comfort levels (occupants well-being). Temperature near the ceiling has been monitored to calculate the thermal gradient into the room during winter season and the energy consumption to maintain a comfort temperature in the volume occupied by people. In order to optimize the heat from plant elements and to reduce the phenomenon of stratification, the remote management system (monitoring, control and regulation) controlled the heating units.

Three different technical solutions were adopted in school Manzetti monitoring activity: for each room of a representative group has been installed heat accounting system to estimate energy consumption and has been indicated indoor/outdoor monitored parameters.

Room 1 represented the active control considering the installation of a technological solution motorized threeway valve connected to an electronic control unit modulating the input flow of fluid into the heating plant element; an occupancy detector activated by control unit manages thermal plant and lighting. In Room 2 it has been installed a thermostatic valve to control set point temperature. Finally the Room 3 represents the base case devoid of a system of thermoregulation.

Technical solutions adopted in the Department for Productive Activities during monitoring activity concerns only two cases: the base case and the active control.

The groups monitoring protocol included summer season and winter season. The electronic management system proposed as innovative technological solution acting on:• remote management of plant elements; • energy delivered by terminals of system plant ;• thermohygrometric parameters in the rooms.

Collecting and recording data system is realized by an electronic platform: the monitoring equipments (sensors and actuators, plant controls etc) are connected to a local control unit located near radiator/fan coil. The local unit communicates with a central unit through the local area network.

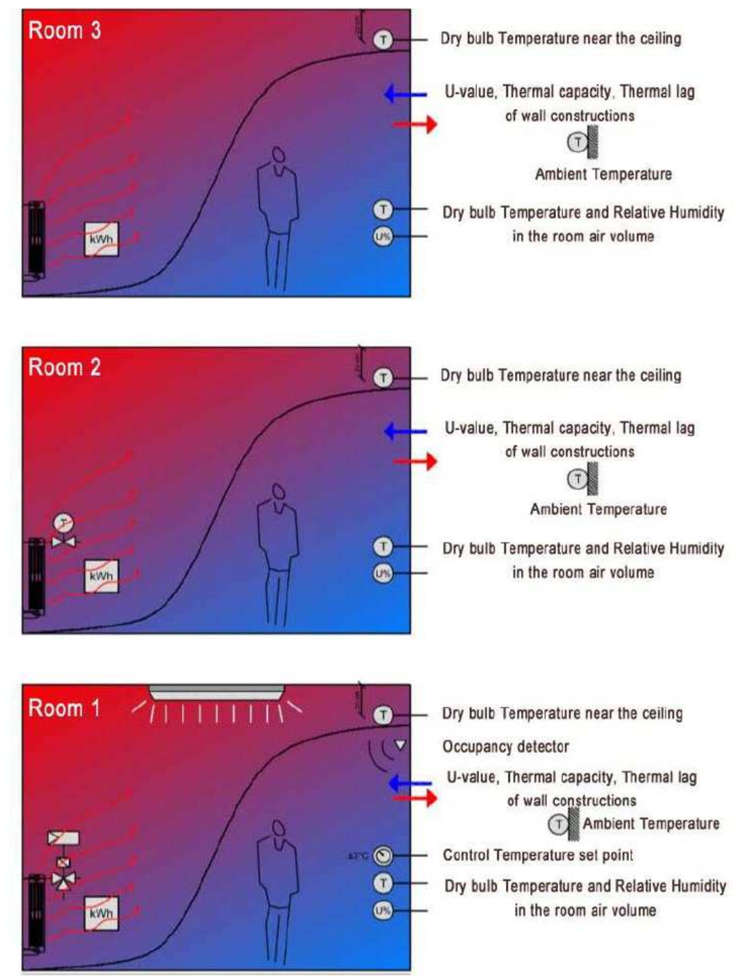

Fig. 3. Technical solutions adopted in school Manzetti monitoring activity for each monitored room. In the picture the curve represents the trend of the temperature inside the room.

Fig. 4. Installation of motorized three-way valve connected to an electronic control unit on radiators (a), on fan coil (b).

Energy analysis results

Dynamic simulation was used to achieve the research objectives supporting monitoring activity by solving many problems due to the uncertainty of monitoring results. During the monitoring activity, the actions of the occupants interfered with the functioning of monitoring equipment, making it difficult to interpret output data.

In the Department for Productive Activities of Aosta, comparing the case base with the new technological solution for thermal plant, monitoring results revealed that the active control produced a real energy saving in terms of economic resources (for example, in the rooms without active control, thermal plant was never switched off during weekends), but it does not solve problems connected with indoor discomfort in workplaces. During winter period in the rooms with North exposure dbT is below the range value for indoor comfort because of the building massive envelope without insulation, with a transmittance equal to 0.85 W/m²K (value above the minimum required by law). Instead rooms of block 2, with a East and West exposure, in addition to high internal gains, benefits of free solar gains thanks to the double glazing facade: monitoring data show the habit of users to manually turn off fan coil because dbT exceeds 30°C throughout all the working period. For the same reason, during summer period fan coil never switched off because of the high temperature due to internal gains and solar gains, especially in rooms with West exposure. About relative humidity, it must be specified that the new building does not have a natural ventilation system and the monitored data shows RH value less than 20-25% with an increase in the perception of discomfort (dry air) during coldest weeks.

MODELLING STRATEGY

As a consequence of the difficulties evidenced in interpreting monitored results, it was necessary use dynamic energy simulations to investigate energy demand expanding survey on full scale building. The input for the energy simulation starts from the description of both buildings as complex systems considering all the environmental and technological aspects in a specific climate: weather data represent the boundary conditions. The analysis approach used in the construction of the buildings analysis models involves the following steps: 1. Identification of building blocks; 2. Analysis of rooms uses; 3. Definition of thermal zones. By definition, an analysis model is a simplified representation of reality: in both cases, it is adopted an approach to the model construction starting from the general to the particular. First was carried out the analysis of construction typology of each building, making possible a division of different blocks each one characterized by structure typology, construction of facade elements, type of heating/cooling plants.

By focusing on each building block, it has been conducted an analysis on room occupancy on each floor: understanding activities taking place within the rooms of a building as a school or a public office is essential for a correct identification of internal gains because they are related to the number of occupants inside the room, the equipments (number of terminals, printers, etc.), type and number of light sources. This analysis is aimed at the subsequent identification of "macro-zones", entities with specific thermophysical characteristics representing thermal zones in the ESP-r model.

In the case of the Department for Productive Activities of Aosta, as a result of a first analysis of exposure, orientation and construction specifications of the building complex, it has been reasonable to divide the building in three blocks for different construction type, thermophysical features of facades, and plants typology (Fig. 5). Since the block 3 is similar to the block 1 for construction typology, thermophysical characteristics of the facades and nalysis

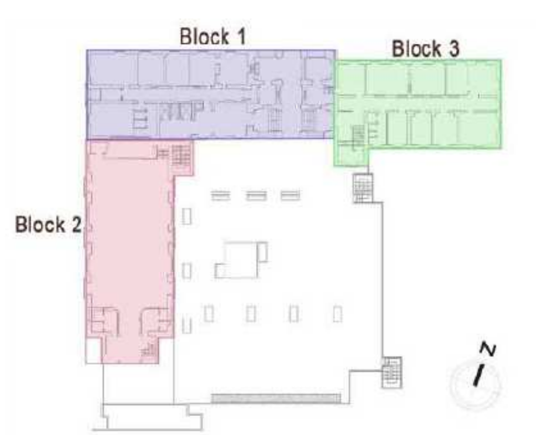

Fig. 5. Plant of the blocks identified in Department for Productive Activities of Aosta.

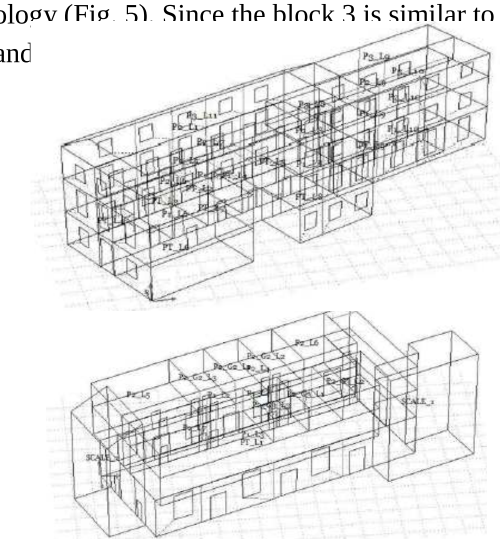

Fig. 6. Esp-r models: Block 1 South view (a), Block 2 East view (b).

consists only in blocks 1 and 2. Each block was divided into a thermal zones, each zone can identify one or more rooms into the building that are characterized by a defined volume of air at the same temperature, with the same construction materials and the same internal gains. A single thermal zone can include rooms with similar aspects: the "similarity" is to be found in exposure, orientation, intended use, housing characteristics, typology of plants.

Therefore, zones conditions are strongly affected by the internal gains connected to the activities/uses of the rooms so, as a base for the analysis model in ESP-r, it was built a volume model indentifying each zone for different intended uses of office rooms [4]. Consequently to the identification of two different blocks it has been created two analysis model, one for each block (Fig. 6). More specifically, for the group of rooms interested by the energy monitoring program, it was decided to represent each room as a single thermal zone in order to be able to compare directly the output data provided by the simulation in ESP-r and the parameters recorded during monitoring. The same methodology has been applied to the Manzetti School, where the planimetry configuration has suggested the identification of two blocks with an L form, similar for orientation, conFiguration, structural typology, and type of plants.

SIMULATIONS

As case of study for the dynamic simulation it is represented the model analysis of the Department for Productive Activities of Aosta.Two different conFiguration files has been created for each block identified in the building complex:

- Block1_base case, consisting of four floors with wall structure with actual heating plant with radiators. No occupancy.
- Block1_upgrade project, the same of the base case considering technological solution for heating plant and occupancy.
- Block2_base case, consisting of three floors with concrete structure and double glazing system for facades at first and second floors. Actual heating/cooling plants with fan-coil.
- Block2_upgrade project, the same of the base case considering technological solution for heating/cooling plant and occupancy.

For assessment purposes, it has been considered several assumptions: reference weather data, construction elements for facades, occupancy and operational schedules, control files of the heating/cooling plants system.

To implement occupant behaviour into the model simulation it has been considered operational schedules to represent windows openings and infiltration by imposing different rate for the ventilation (Air change per hour) based on daily profiles for heating and cooling period.

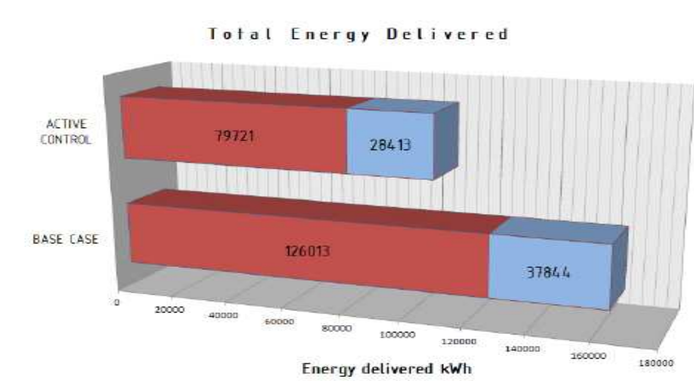
RESULTS OF ENERGY SIMULATION

The results of dynamic simulation carried out on the Department for Productive Activities focused on two aspects:

• Total energy delivered, the thermal energy required for each building considering the application of the heating and cooling system control devices and the energy consumption [5] ;

• Indoor comfort of occupants in workplaces.

Simulating results, according with monitoring results, revealed that the active control produced a real energy saving. During winter period (15 October-15 April) and during summer period (1 June - 15 September) in the base case total energy delivered is 163857 kWh; considering the introduction of an active control on thermal plants, total energy delivered in 108134 kWh, obtaining an energy saving of 34.2%. (Fig. 7).



control.

Thermo hygrometric conditions: Winter Period

To investigate thermohygrometric conditions of the representative rooms with different exposure in the simulating model (the same rooms selected for the monitoring activity), it has been compared dry bulb temperature, relative humidity and zone resultant temperature to show the difference between the base case and the active control (data refers to a tipycal week in winter period). (Fig.8)

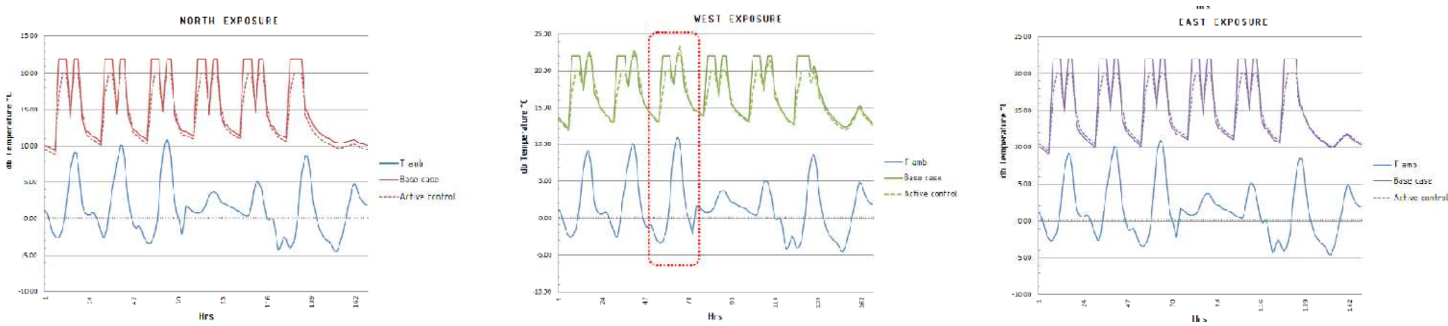


Fig. 8. Zone dry bulb Temperature comparing base case and active control in rooms with different exposure

During the winter period, when radiators/fan coil are switched off, db temperature is affected by the trend of ambient temperature. During the nigth and the weekends db T decreases significantly because of athe heat losses through the external wall. Thermohygrometric conditions of the room with a West exposure are better than the other rooms thanks to the contribution due to the direct solar radiation trought the double glazing facades; dbT with active control often exceeds T setpoint because it has been considered internal gains.

Relative humidity is the more significant parameter to describe thermo hygrometric comfort of zone in which people leave and work, and it depending on the extent of internal gains within the zone. Assuming occupants to be sit and working into office room , relative humidity values have to be 40-60% corresponding an intern dry bulb temperature of 20-22°C. Considering the simulating model used to establish energy saving due to a specific tecnological solution on thermal plant, the simplifying assumptions made on occupancy in the base case do not allow to compare RH values between base case model (no internal gains) and active control model (considering occupants and equipments). RH results are shown in Table 1a.

The zone resultant temperature of a room, T Res, is a useful parameter to describe indoor comfort and it represents the average between the dry bulb internal temperature and the mean radiant temperature of the walls in a zone. T Res values are shown in Table 1b. T Res values are always lower than comfort range values. Only in the case of west exposure, in the early hours of the afternoon, T Res reaches 21-22 °C when the internal surface temperature of the double glazing facades increases thanks to the direct solar radiation.

Table1. (a) Relative Humidity and (b) Zone Resultant Temperature comparing base case and active control in rooms with different exposures. * RH m and TRes m represent the mean value calculated on a period limited to the working hours.

Relative Humidity						
	Base case			Active control		
	RH max (%)	RH min (%)	RH sq (%)	RH max (%)	RH min (%)	RH sq (%)
North exposure	52	16	22	55	19	35
West exposure	43	16	20	44	18	26
East Exposure	49	16	21	49	16	29

Zone Resultant Temperature						
	Base case			Active control		
	TRes Max °C	**TRes Min °C**	**TRes sq °C**	**TRes Max °C**	**TRes Min °C**	**TRes sq °C**
North exposure	18.8	10.0	17.3	17.3	9.5	15.9
West exposure	21.8	12.8	19.5	22.3	12.5	18.6
East Exposure	19.3	9.6	17.4	18.0	10.0	16.5

In general, thermo hygrometric conditions of room with West exposure are better than the other rooms with different exposure thanks to the direct solar radiation trough the double glazing facades. Internal surface temperature of the double glazing facades with West exposure is significantly affected by the trend of direct solar radiation graph .

The internal surface temperature values for the other exposures are lower than the previous case: in particular, in room with North exposure internal surface temperature is almost constant because of the lower thermal capacity of the non insulated external wall and it does not exceed 14 ° C contributing significantly to the decreasing of the operating temperature within the room.

Thermo hygrometric conditions: Summer Period

During summer period it has been considered rooms with East and West exposure because the room with North exposure, located in the Block 1, is provided of radiators for the winter heating only.

According with monitoring output data, in the base case it was assumed that fan coils never switched off during the weekend, so the difference between base case and active control is more evident during the weekend when db T is free to float producing rooms overheating. (Fig. 9)

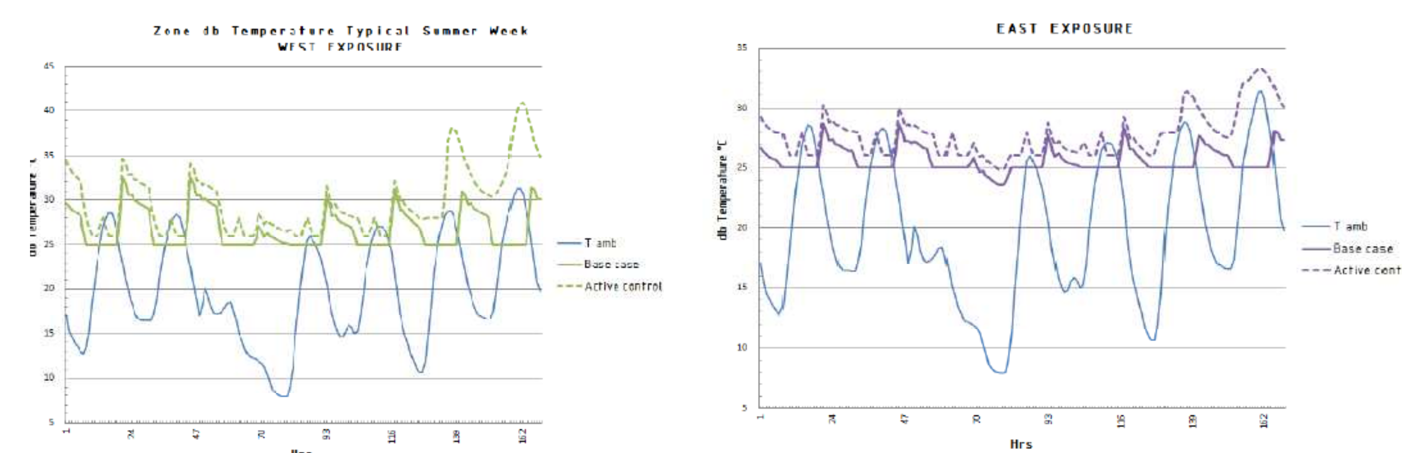

Fig. 9. Zone dry bulb Temperature comparing base case and active control in rooms with different exposures

During the morning, dbT increases over 30°C when fan coil switched off. In relation to the problem of summer overheating, the addition of a shading system has a positive effect to reduction of the temperature of to indoor surface of the double glazing façade with the aim to prevent the direct solar radiation to penetrate inside the rooms. Even if this solution produces an improvement of indoor comfort bringing intern dry bulb Temperature values closer to the comfort range during working hours, there is a large gap between inside and outside temperature.

As a second hypothesis, it has been studied the effects of night cooling on indoor thermo hygrometric conditions. It was used a detailed geometric model of a room considering active control solution and the worst conditions of exposure (West exposure). The room has been divided into two thermal zones, where the zone_1 represents the volume portion of the false ceiling (Fig. 10a); two ventilation opening grids have been introduced at the top and at the bottom of the room and it was created an airflows network [6] with a scheduled control (Fig.10b).

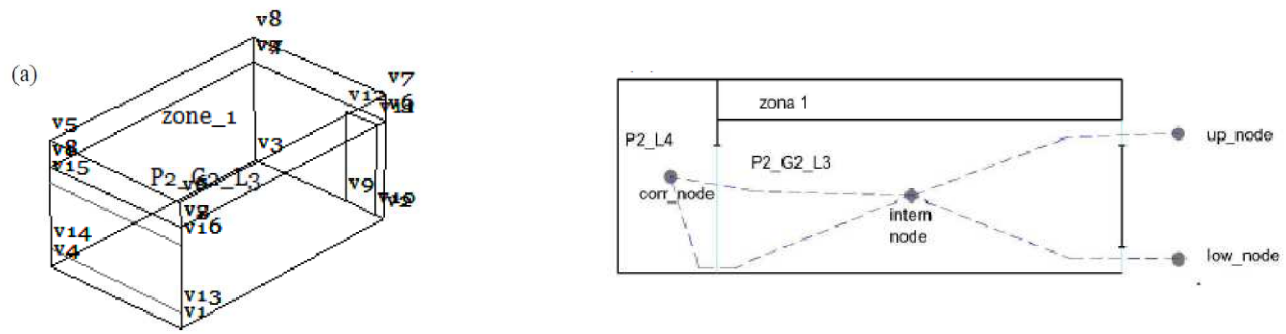

Fig. 10. a) ESP-r model of room with West exposure adding ventilation grids; (b) Airflows network diagram to represent natural ventilation in the room

It was performed a simulation of db T comparing three different strategies to solve summer overheating:

- Active control, considering the cooling plant only;
- Shading system, introducing a shading system to the windows to protect the room from direct solar radiation;
- Airflow network, considering all previous strategies and natural ventilation (night cooling).

Db Temperature decreases significantly thanks to the addiction of a shading system to the transparent facades. The addiction of a natural ventilation system does not have a significant improvement on thermo hygrometric conditions within the room: the gap between Zone db Temperature and Ambient Temperature in still high during the night (Fig. 11a). About Zone Relative Humidity, natural ventilation maintaining RH value within the comfort band (40-60%).

Stronger airflow will be induced when there is a large vertical distance between inlets and outlets openings, and when there is a large difference between indoor and outdoor temperatures.

In this case natural ventilation was not sufficient to activate an airflows convection in the room because of the small distance between opening grids placed at the top and at the bottom of the room. Moreover, the west front is also not directly exposed to the night breezes, infact the main wind direction in July and August is South-North. For these reasons the only good solution to improve the indoor comfort in the rooms of the block 2 is the use of external solar shading on the double glazing facade or a new technological solution for the facade.

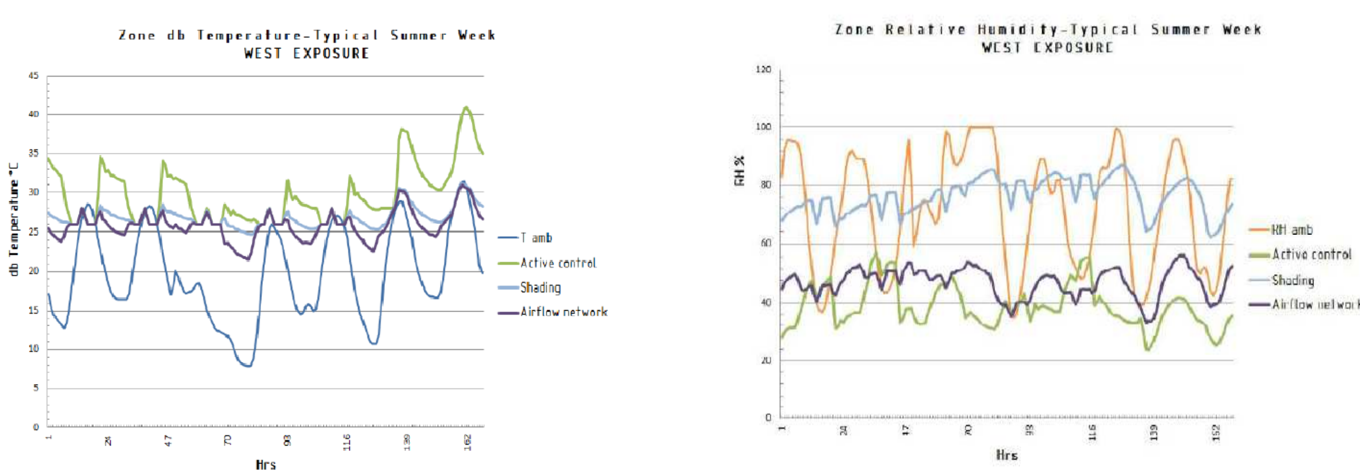

Fig. 11. Zone Dry bulb Temperature(a) and Relative Humidity(b) comparing three different strategies to reduce summer overheating.

CONCLUSIONS AND FURTHER RESEARCH

This research shows a methodology for evaluation of full scale building energy behaviour considering results obtained from monitoring activity and dynamic simulation. Simulation tools allow to investigate different scenarios to improve the building performance and comfort indoor.

An important aspect considered it has been the detail of the model simulation: in the case study it was decided to adopt "multi-zone" model to evaluate the environmental performance for a specific thermal zone and to extend results to the full scale the building . This approach offers the opportunity to verify the impact of a technological solution on the energy behaviour of a full scale building minimizing the complexity of the model simulation and consequently the possibility of making mistakes.

According to the results of model simulation of Department for Productive Activities, the main energy consumption is due to the new building (block 2). Considering the retrofit of building throught an improvement of thermal plant in order to reduce energy consumption, it is reasonable to introduce the active control for fan-coils only. In fact, installing an active control system on radiators of block 1 is much expensive because it is necessary to change the hydraulic connections on each unit to insert three-way valve. Considering the introduction of an active control in fan-coils of block 2, the estimated value of energy saving is about 25-35%. Installation cost for each room is 1100-1200 euro, and considering max 2 fan coils within a room, total cost would be about 40.000 euro. However, active control does not provide the solution to the problem of indoor discomfort due to the double glazing facades in office rooms located in block 2, especially in the summer period. In this case the the most cost-effective ways to improve building energy performance and comfort indoor is the building envelope retrofit through the investigation of different technological solutions for facades system.

ABSTRACT

As one of the largest developing countries in the world, China is undergoing a period of massive construction. Meanwhile, the urgent energy intensity reduction agenda requires energy efficient and environmental friendly design to be implemented nation-wide. Specific guidelines and green building assessment system have been established in mainland China. This study will review two LEED awarded projects in southern and northern China, to reveal how the “LEED-oriented” practice came to success through decision-making, design strategies and specific system integration. The design team adopted new mindset and methods in their practice and benefited the projects: 1. Pre-project decision-making; 2. Performance-based design; 3. Integrated system approach. Energy efficient systems and green design features introduced great customer experience with low energy cost. The paper offers technical project details. Quantitative data from post-occupancy survey are provided to investigate the actual performance of the operating systems and explore the possible issues; occupant satisfaction is also being studied. Through case projects, it was showed that leading edge green building assessment systems help to identify the general structure for environmental issues and increase public awareness in developing countries. Certain limitations of existing practice are discussed, and suggestions on enhancing green building design practice in developing countries are summarized.

INTRODUCTION

China is one of the biggest developing countries in the world and facing the challenging energy and environmental issues. Estimated by the World Bank, half of the world’s new construction will take place in China up to 2015. With such rapid developing speed, the released International Energy Outlook (U.S.EIA, 2011) predicted that about 50% of energy consumption grow will be come from China and India in the next 2 decades. At the same time, national and local environmental problems have manifested along with the resources shortage. Eight of Chinese large cities have been rated as the top-ten air pollution cities in the world; nearly 2/3 cities in China facing water shortage and in particularly severe areas water resource per capita only reaches 4% of the world’s average. With all the above and similar developing issues and problems being brought to the surface, the Chinese government has announced an aggressive energy intensity reduction agenda which has set the carbon emission reduction target to be 40%-45% up to 2020, comparing to the 2005 standard. In China, about 25% of electronic use goes to building consumption including lighting, cooling, heating and cooling. The energy reduction target sent a strong signal to the industry to speed up the “green building evolution”. The rising attention and the government’s support have driven the environmental practice in China and as well as the development and implementation of building code and green building evaluation systems.

Local green building evaluation systems have been established in China. The Green Building Evaluation Standard (GBES) was created in 2006, and in 2003 the Building Assessment System of 2008 Green Olympics was developed to offer guidance on green practice in stadiums and supporting facility construction for the 2008 Beijing Olympics event. At the same time, several comprehensive foreign evaluation systems have entered China; the most well-known “Leadership in Energy and Environmental Design” (LEED) system has rapidly dominates the market of green building certification in the recent years. Based on the most updated data posted by USGBC, for the top ten countries with offshore LEED projects, China is at the third place; there are 1156 registered and certified projects in mainland China with the total building area being 66.5 million gross square meters. In the certified projects, nearly 70% were awarded LEED Gold or LEED Platinum. Professionals in the industry also endorse the system, the number of LEED GA and LEED AP reached 1,092 (1% in the world) in mainland China, ranking at the third place. 30% of these registered LEED professionals are architects; the rest are consultants, planners, engineers, and interial designers. It can be seen from these data that LEED system has leading the field of green building evaluation in mainland China.

With LEED and its method been introduced to offshore areas, questions have been arise on how does the system address the “acclimatized” issues in developing countries, especially some Asian regions with distinct cultural context. More research attention should be placed on strategies of refining the green building evaluation systems to better serve the industry and promote the green development in these developing countries.

Figure 1 left: Vanke Center (Shenzhen) was certified LEED Platinum award; right: Linked Hybrid (Beijing) was certified LEED ND award

OBJECTIVE AND METHODOLOGY

Through two "LEED-oriented" projects in mainland China as case study, this paper would first demonstrate how pre-project target setting and performance-based integrated design let to LEED-awards and occupant satisfaction. Secondly, base on post-occupancy survey, actual energy performance of the LEED-certified buildings will be investigated. Project information including technical details, energy data, operation cost, and occupant feedback will be revealed in the paper. Successful target-oriented working mindset of these cases will be summarized and how far would the LEED system guides the projects to the energy-efficient outcome and some possible limitation will be discussed. Suggestions on refining the green building assessment systems in developing countries will be offered at the end of the paper.

CASE STUDY: LEED-ORIENTED PROJECTS

The two LEED-awarded projects selected for case study are the Linked Hybrid, Beijing and the Vanke Center, Shenzhen (fig. 1). Steven Holl Architects designed both projects with consistent design mindset. These two projects locate in different climate zones and facing varying environmental issues; yet pre-project target setting and performance-based integrated design successfully let the projects to LEED awards. The Vanke Center, Shenzhen and Linked Hybrid, Beijing are rewarded LEED Platinum and LEED ND respectively.

1. Pre-Project Decision Making

In both of the projects, client and the design team had set their goal on LEED award at the pre-project stage and the green design strategies were worked out based on the environmental structure in LEED. Showing in Table 1 is the crosscheck shortlist of the rating environmental aspects in LEED and the green design strategies in Vanke Center.

Table 1 LEED-based green strategies employed in Vanke Center

Required Aspects in LEED	Green Strategies in Vanke Center	
	Design aspects	Systems and strategies applied
Sustainable Sites	Sustainable site selection	traffic, climate, and views
Water Efficiency	Water saving	rainwater collection and grey water system
Energy and Atmosphere	Building forms	floating structure for ventilation,
	Envelop design	Adjustable shading system
	Energy systems	thermal energy storage technique CO2 monitoring system under floor air distribution system solar water heaters and PV panels ground level greening and slope green roof efficient lighting design
Materials and Resources	Materials	local and renewable materials recycled and reused products waste management and reclaiming in construction
Indoor Environmental Quality	Indoor quality	low-radiated materials Adjustable ventilation system

The expectation on the "green performance" of the project had been welled defined at the pre-design stage. With the clear target, the green design of the project was improved and the efficiency of design-construction process was increased.

Despite the significance to the industry, green practice is at the starting stage in many developing countries. From the Vanke Center case, it can be seen that LEED offers comprehensive direction and clear environmental structure for green practice in developing countries, and greatly speed up the local green development.

2. Performance-Based Design and System Integration

The second case is Linked Hybrid, Beijing, which was awarded LEED ND in 2011. The selling point for the apartments in Linked Hybrid was the 'constant temperature and humidity' living environment: comfort and relatively constant thermal environment would be provided in the apartment with the temperature ranging at 20-26℃and humidity within 30-70%; acoustic control at 35-45db level. This performance was achieved by the system-integrated design. One set of geothermal power system, ceiling radiation, and the fresh air supply system offer comfort indoor experience and outstanding energy performance in Linked Hybrid.

- Geothermal Power

In Linked Hybrid, a large geothermal heat pumps system has been installed to achieve high energy efficiency. Geothermal system is known as the most advanced energy utilization plan; it takes advantage of the temperature consistency and heat storage of the earth. The system CUP can be as high as 5-7; while air-conditioning usually has CUP of 2.5-3.

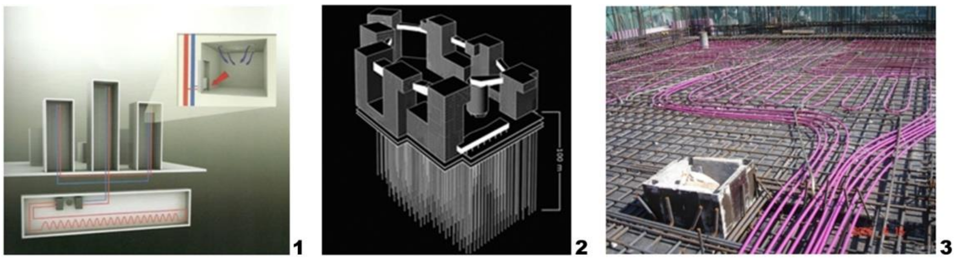

Figure 2 System integrated design in Linked Hybrid. (1) Combination of geothermal system and ceiling radiation system in Linked Hybrid; (2) The geothermal system installed right under the foundation of the Linked Hybrid apartments; (3) Water pipe layout for ceiling radiation system (under construction)

A typical geothermal heat pump system includes 3 parts: the ground heat exchanger, the heat pump unit, the delivery system. In Linked Hybrid, the ground exchanger is formed by 632 water pipes. The system buried right under the garage floor and reached 100m deep. The geothermal system uses the PE “DN32 double-U” pipes to run the water, which are lying every 5m in grid array, between the anti-floatation piles. This is a closed-circuit loop, and materials with large heat conductivity is used to fill up the gaps surrounded the heat exchange pipes. Every loop is formed by 6-8 water pipes, and 5-6 loops are ended in one water supply and return header. PE pipe with an expected 50-year life circle were employed to minimize the maintenance; and during construction the pipes had gone through multiple pressure tests. If leakage happens during operation process, the particular loop in problem can be shut down in the inspection camber. By placing the system right under the building’s foundation (See fig.2), Linked Hybrid project started the practice of installing geothermal heat pump in core urban areas.

With its delivery system, the geothermal power offers constant indoor comfort for apartments in Linked Hybrid. There are 8 heat pump units in the system, 4 units are used to heat up/cool down the fresh air ventilates; while the other 4 units of 1200kw are used for the ceiling radiation system. In most of the year, the system works alone to supply cooling and heating to the 220,000m^2 in the neighborhood. Only in the coldest or hottest months, extra power supply from boiler and cooling tower would be needed. Water was circulated in the pipe array inside the ceiling structure and heat radiation from the ceiling would regulate the temperature in the apartment. In summer, 30 °C warm water is cooled down to 25°C by heat exchange with ground and further cooled to 18°C by the heat pump unit to circulate in the ceiling radiation system inside each apartment. In winter the original water temperature was 3°C and would be heated up to 8°C by the ground heat and goes up to 31°C by the heat pump unit. To deal with the peak period, 2 refrigerators of 2000kw would be added to assist the geothermal heat pumps and cool the water to 7~12°C in mid-summer. For the coldest months, 4 boilers of 1400kw would be provide extra power support; and 45~50°C water will be running in the loop system to offer radiation heating in the apartments.

The structure for the ceiling radiation system was formed by 2mm thick PB plastic pipes with the outside diameter being 20mm; all these piles were installed as a layer of the ceiling slab (see fig. 2 and fig. 3). The water circulated inside the loop is around 18~21°C for refrigerating in summer and up to 28~31°C for heating in winter. Inside the ceiling slab, the water pipes are lying more densely at the north side than the south to offset the difference caused by orientation; and a more uniform thermal environment will be created in the apartments. The year-round indoor temperature is between 20 to 26°C in the apartment. At the same time, the ceiling is insulated from other parts of the envelopes, such as the partitions and external walls to avoid heat loss.

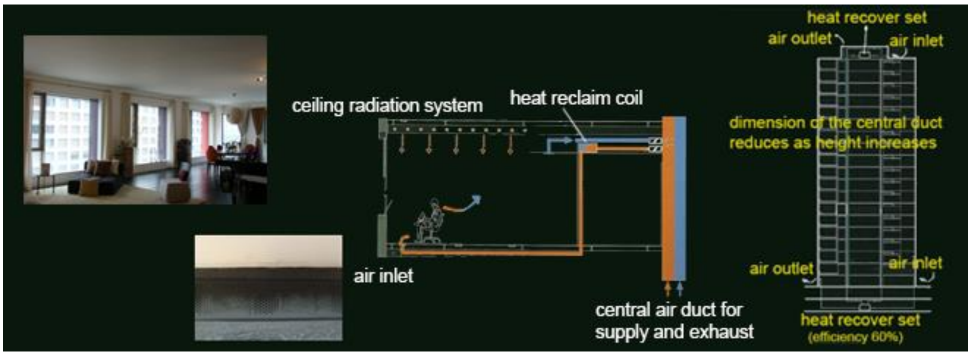

Figure 3 The separated indoor thermal regulation system (ceiling radiation) and fresh air supply system in Linked Hybrid *(modified based on Grand Moma by Steven Holl Architects, Beijing Press*)

In terms of indoor thermal regulation, the ceiling radiation is more energy-efficient comparing to the traditional air-conditioning system, as water has a larger heat capacity and is better medium of energy than air. To maximum the performance and energy efficiency, the thermal regulation system was separated from fresh air supply in the project. A "low turbulence, low mixing, low cooling" fresh air supply system was installed in the apartment. In each hour, 300m^3 volume of fresh air is sent to the apartment, which is much higher than the current national standard of fresh air supply (30m^3/person.hour). The system allows non-mixing heat exchange between the used and fresh air; 60% heat from the used air can be reclaimed by the system to pre-heat/pre-cool the fresh air before it enters the apartments. The geothermal system supports the heat reclaim set in the building. In summer, the fresh air is cooled to be 2°C lower than the indoor temperature and has been humidified. The section of the air shaft would become narrower every 3-4 floors to avoid air pressure decreasing and stabilize the wind speed (fig. 3). The design has saved both material and power on air pumping.

The system-integrated design has also been applied in the Vanke Center Shenzhen. In the project, an ice-storage system was employed to support the air-conditioning in summer months. The system uses electricity to make ice and store energy during night-time hours, and this energy will be released and provide cooling during daytime hours. The system has two advantages. First the system operates at night and avoids the load peak of the city power network. Second the system would have higher CUP comparing to air-conditioning cooling, as it uses water as heat medium instead of air. Under floor air duct network was installed to deliver the cool air to different components of the building. Cool air comes out at ground level and fills up the space up to about 2 meter height; such design increase the efficiency of the system as the cooling energy was distributed within the domain of occupant activity (fig. 4). A CO2 monitor is connected to the system and the airflow at the fresh air inlet would be adjusted based on the indoor air quality. Heat recover set was installed to collect waste heat from used air for fresh air pre-cooling.

Figure 4 The air outlets in the lobby and offices in Vanke Center

Vanke Center takes full advantage of solar energy. Solar water heaters and PV panels were installed on the large green roof (fig. 5). The solar water heaters supply hot water to the swimming pool and bathrooms. The large amount of PV panels is expected to provide up to 15 percent of the total energy need of the building and estimated annual output is 280,000 kilowatt-hours. The power generated by PV panel will support the dehumidification and refrigeration systems in the building.

Figure 5 Solar water heater and PV panels on the roof

Great amount of energy consumes on lighting in the office building (Irish Energy Centre, 1995). An efficient lighting design in offices can save energy remarkably. The project combines daylighting and high efficient luminaries and induced lamps in the lighting design. The building has large double-glazing facade to allow sufficient daylight to enter the offices. A set of perforated louvers is set up to provide certain level of shading to the facades, and its angle can be automatically adjusted according to the solar attitude or manually operate by occupants based on the need (fig. 6). Meanwhile, daylight has been integrated in the system where the requirement on stable lighting is less strict, such as underground parking; or in some places the daylighting is combined with the artificial light as a delicate supplement (fig. 6). Some of the open space was well designed so the source of nature lighting will not be blocked.

Figure 6 Left: the application of daylight in the lobby and underground space. Right: The external shading device and adjustable perforated louvers

3. Post-occupancy survey and occupant satisfaction

Rare data on post-occupancy building performance and operation cost was reported for LEED awarded buildings. Post-occupancy survey is essential for green design enhancement and reveals whether the systems and green design feature could function properly. Satisfaction of occupants and their behavior pattern in the buildings offers valuable reference for architects and benefits green practice.

The energy system in Linked Hybrid combines the geothermal power with boiler and cooling tower. The EMO manager of Linked Hybrid stated that in most of the year, the geothermal system could fully cover the neighborhood’s demand in cooling and heating. In the coldest and hottest months, extra support is applied. This system cost 50% more than a standard energy system, but running in low operation cost with outstanding energy performance. Table 2 shows the initial investment and operation cost of different energy systems in mainland China. A survey was conducted when the integrated system in Linked Hybrid had been running for 12 months to supply heating and cooling for total 220,000m2 areas. According to the Estates Management Office, the electricity peak occurred in January and February, during these winter months the operation cost of the system was 700,000RMB/month. A close number has been recorded in June and July. This number has already included the energy used for boiler and cooling tower, namely, it is the total cost for heating and cooling in winter and summer. May and October had the lowest consumption according to the records. The electric bill for these two months is about 350,000RMB/month. The annual operation cost on cooling and heating for this neighborhood was approximately 6,000,000RMB.

Table 2. Comparison on initial investment of different energy systems

Initial Investment		Operation Cost	
Gas turbine	8,300 RMB/KW	Gas	0.18 RMB/KW
Chiller/Heat pump	3,600 RMB/KW	Electricity	0.40 RMB/KW + 50 RMB/KW(peak)
Compression chiller	3,200 RMB/KW	Water cooling towers	14 RMB/m^3
DE-Absorption chiller	4,250 RMB/KW	CO_2-emission	4,250 RMB/KW
Cooling towers	500 RMB/KW	Gas	0.2 tCO_2/KWh
Boiler	450 RMB/KW	Electricity	0.9 tCO_2/KWh
Energy piles	2,000 RMB/KW		
Ground water wells	700 RMB/KW		

When the building was put into operation, the Vanke people were happy to see that the thermal storage system, the under floor air distribution system brought thermal comfort to the building and had a better energy performance with lot money saved on electric bills. The solar PV panels offer 15% of the power for the building and reduce the CO2 emission. Water saving strategy saves 30% of the total consumption. The innovation of the construction of the project saved 80,000,000 CNY budget.

To allow the user to be in control of comfort and operating the system is essential for saving energy and operation cost, and more importantly, to achieve occupant satisfaction. People can stand some degree of discomfort when they are in control of the conditions in their workplace (Cohen et al., 1999). Yet to what extend should the occupants be granted the control worth discussion. When user involvement is not appropriately designed, it can also result in wrong operation of the building and wasting energy. Leaman's study (1999) revealed that user reaction and response could be reckless sometimes, such as over-compensating for relatively minor annoyances, not choosing the most proper system to operate but instead the ones that are convenient to hand, and lacking responsiveness in adjusting the systems with the change of the environment.

In the Linked Hybrid case, occupants can regulate the temperature and fresh air supply by a controller inside the apartment, which has a limit though, considering the comfort range and energy consumption of the ceiling radiation system. The integrated system set the temperature range to be 21-22 ℃ for winter and 24-26℃ for summer, occupants can adjust the indoor temperature within 2 degree. When the apartment is unoccupied for couple days, the system can be switched off while small amount of fresh air will enter and circulate the space due to the pressure in the duct. So the apartment is still ventilated without extra energy consumption, and there won't be unpleasant smell when occupants come back days after.

The energy system of Vanke Center showed a slightly different picture. Data from EMO recorded the total energy output of the PV panels was 1358,460KWh since the building was put into operation, and the annual output of the system was 272000 kWh, reached about 97% of the expected value. According to a recent interview, the EMO stated that after 5 yearss' operation, the PV panel system has been malfunctioned and under repair. On the other hand, test result from 2013 revealed that the ice store air conditioning system had a low efficiency in ice making (less than 50%). The data above demonstrates the performance of the energy systems in Vanke Center are not functioning as designed.

Nevertheless, the design of Vanke Center values the comfort and satisfaction of the occupants. Great efforts were made on different aspects to meet the comfort range, including temperature, humidity, lighting and views. Occupants can flexibly control the working environment according to their personal needs. In the working space sparated lighting switch and a control panel for air conditioning are provided to each staff. "People working together in a big office usually have different needs for air-conditioning. a centralized cooling system hard to satisfy everyone and sometimes makes people sick. Now this is no more a problem to us." A staff claimed in the interview. Furthermore, everyone working in the building is more or less noticed the building's green features. It shows that understanding how the building operates and its quality of being environmental friendly brings additional satisfaction to the occupants.

DISCUSSION ON GREEN PRACTICE AND EVALUATION SYSTEM ESTABLISHMENT

These two case studies demonstrated that LEED and LEED-initial practice benefits a the green building development in mainland China, and the positive effects can be summed up as below:

1. The LEED system offers clear environmental structure for green practice and in developing countries;
2. Training process and technical support introduce knowledge input and increase the amount of local professionals;
3. Large and demonstration projects can promote international cooperation and communication between different expertise.

However, the high cost and large investment of these LEED-oriented projects make it difficult to widely adopt this mode in developing countries. Energy performance of some of the LEED projects are relied on high-tech systems, and these projects to some extend, neglect the passive design and environmental planning methodology. This, as revealed in the case study, has its shortcoming. Based on the above, suggestions on enhancing green practice in developing countries are summarized:

- climate-based passive design

A great portion of developing countries and regions locate in severe and harse climate zones. To identify the climatic issues and formula strategies of climatic design with passive approach is vital in these regions. It is regional-applicable and much less cost-demanded; and a larger cost-and-return ratio can be obtained from climate-based practice in these regions than it was in the moderate climate zones.

- energy efficiency of heating and cooling systems

As Chmutina (2010) has pointed out, improve the cooling and heating system can save up to 70% of energy in China; energy efficient heating and cooling system is essential for the green development in China. Since air carries relatively less energy per unit volume, it is not recommended as energy medium. Furthermore, the heating and cooling system should be separated from fresh air supply.

- standard setting and occupant behavior study

User involvement is essential for both energy saving and occupant satisfaction. The "comfort" standard should be set as an acceptable range instead of a neutral condition; at the same time allow the occupants to adjust the systems within this boundary. It can firstly let the user have the control, and secondly avoid energy waste caused by overreaction of the users. At the same time, branching and operation systems are preferred to centralized control.

Topics: Control Techniques for Energy Management, Building Reuse and Refurbishment
Keywords BESS, Building energy, Peak Shaving, Electric energy, Energy pattern

ABSTRACT

The battery energy storage system (BESS ENERGY STORAGE SYSTEM) is afford storing electric energy of the light load zone release time of the maximum load that may be referred to enable the device .Technical problems in the past due to cost and practical application of the burden to have had a lot of trouble. Due to recent advances in electric vehicles and energy storage devices, the weight of the product density , and product price declines to bring such products to use the matching conditions favorable due to recent social product is applied in many areas and the study who being accelerated. The installation of the battery energy storage products is the maximum energy load of the building users and the required time for the charges to enable the effective use of energy in the building to ease the economic burden of the users have had the energy to give energy providers the burden on the facility expansion this can be a benefit by reducing each other can be described as a method. In fact, the electrical energy storage facilities near field can be said more, but the actual large office building in the applying existing facilities and use of electrical energy for the estimation of the amount provided by the Institute of Energy Research, public buildings energy relative coefficient is used to obtain and afford the actual usage pattern by comparing the work proceeds. Electric energy savings and light load hours of the base rate and the maximum load of the electric peak shaving time by looking at how much it costs to save energy costs and payback period of the initial investment products see if how much can be said for the research .

1. INTRODUCTION

Recent forms of distributed renewable energy power supply is enabled to store electrical energy in an energy storage device (ESS, Energy Storage System) is increasing the interest .The advent of high-density high-efficiency conventional rechargeable batteries store electricity in many areas, it is impossible to escape from what used to be trying to promote. The use of the electric energy storage technology, especially since the maximum power demand on the energy to move the load to a light load zone that enables the necessary electric power demand of the facility for enabling efficient operation. In terms of the power demand of the energy provider by enabling the administration of the generator and the environmental problems caused by expansion of the transmission and distribution equipment, such as to reduce the investment cost can induce a strategic electricity supply. Construction of the electrical energy storage system in order to examine the storage medium should be on the preceding study, regeneration of energy storage in order to find the most suitable medium and utilizing the analysis of the characteristics of each medium should be applied.

2. METHODS

In this paper, the basic structure of the ESS and the ESS for different kinds of features introduced and examined with respect to domestic and international market trends. In addition, ongoing trends related to domestic and international standardization want to analyze the characteristics of the system. These previous studies of one of the devices after the ESS technology applied to the BESS system by looking office building heating and cooling energy peak load management can respond effectively to make sure that after viewing the parties to this paper.

Due to changes in electricity tariffs rising cost of energy use in buildings

Analysis of the building's energy use patterns destination

After application of the ESS destination building operational analysis

The resulting value of destination property derived

3. COST OF ELECTRICITY

If the time zone differential of seasonal fare and each season depending on the hourly cost of the power supply to charge a differential fee system can be said. In other words, in the case of the summer season, winter, spring, fall is divided into 24 time zones, separated by time sensitive afford each season, and the differential rates will apply. Korea Electric Power to supply the exclusive sales structure. Therefore, consumers can choose power bill narrow. Korea Electric Power provides electricity to the unit price, and the average fee structure by use of the following can be classified as shown in the table.

Energy price	~2012	2013
Summer Season		
Spring, Fall Season		Winter Season		
4. ANALYSIS OF THE BUILDING'S ENERGY USE PATTERNS DESTINATION

4.1 Analysis

Location: Daejeon, 139 West seonsaro   Completion date: 12/10/1997

< Land area >   (Unit: ㎡)

Total	Construction area	Green area	Other areas
518,338	28,703	259,604	230,031

Building Structure: Steel Reinforced Concrete

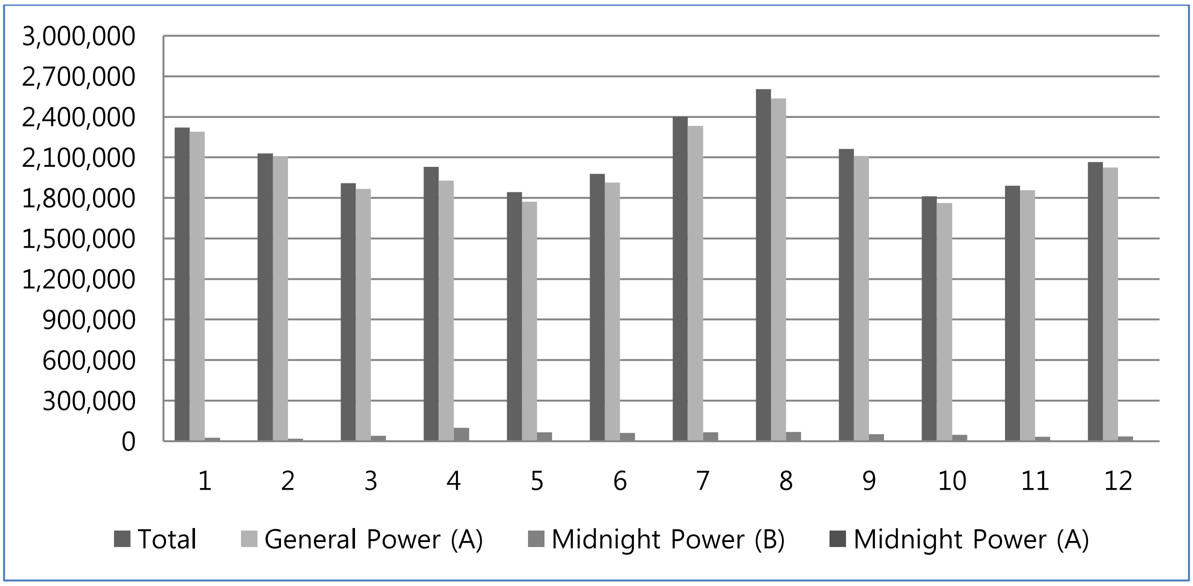
Building Size: 2 underground floors / ground 20 floors

Maximum height: 91.9m, Above is: 36.22N, The floor and: Typical floor 4.2m, up to 5.4m (ground floor)

4.2 Data

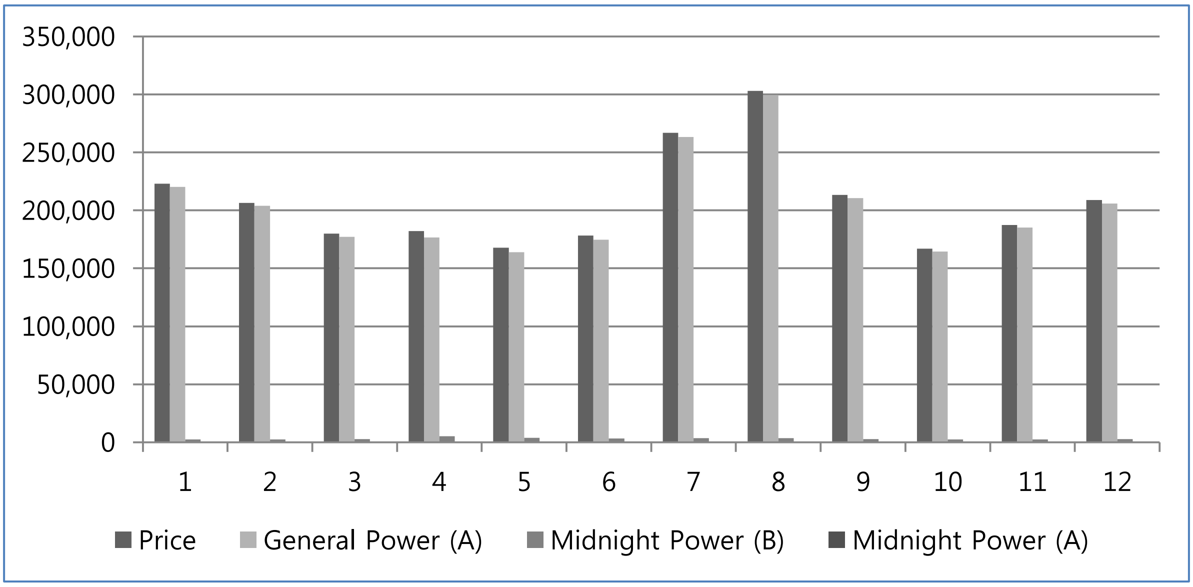
Monthly amount of electrical energy in 2009

(Unit: kWh)



Monthly amount of electrical energy price in 2009

(Unit: Dollars)

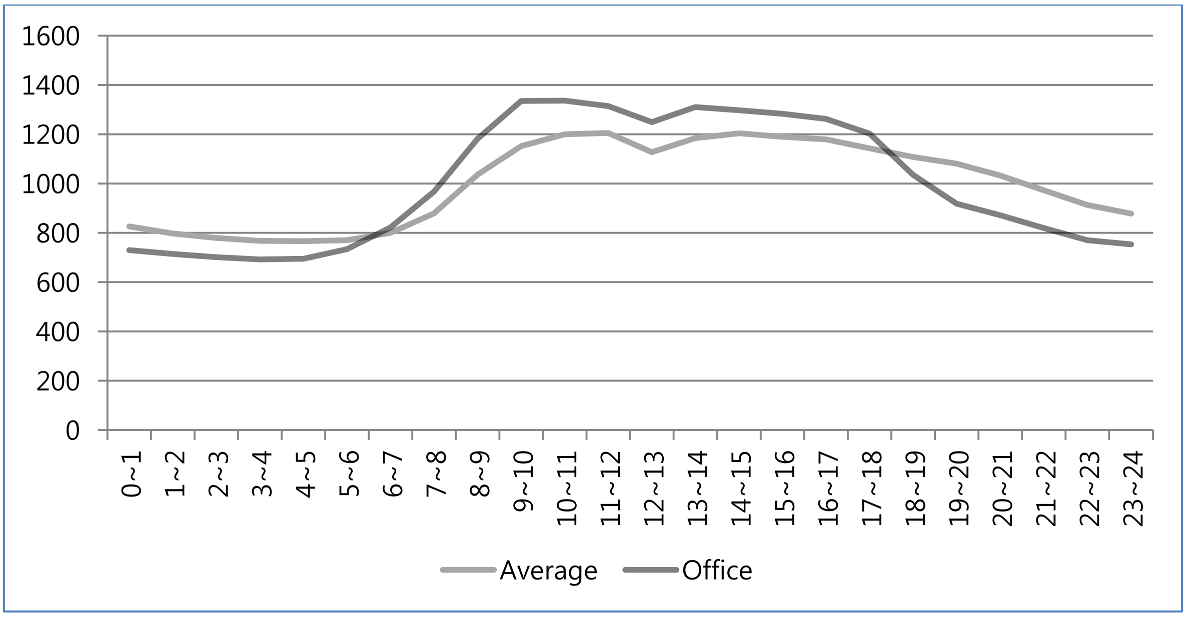


4.3 Solving the building energy use pattern

According to the data extraction KEPCO contract type sales database of customers to find out the average hourly power consumption can be seen. In order to calculate the predicted values relative load factor is the monthly Energy Management Corporation load pattern of educational holiday season working load pattern is used.

Load forecasting = peak demand × relative factor

24 hours relative load factor set to 1000, the average of each time slot representing a load index. How to calculate the relative coefficients are as follows. Classification by type of weekday working and living in the form of electricity usage behavior will be classified by considering the impact. National Day of the week from Tuesday to Friday, the day of the week, not working day-to-day work was set takes place. Working day by working day by day to show a different behavior on Sunday, Saturday and Monday were classified. Closed on Sunday conducted the day of the week as a whole , and performed according to the five-day workweek on Saturday and the other working day and appear in the form of the load is carried entirely closed on Sundays and also the load of the different forms of the need for analysis elsewhere there. 24 hours, the average load factor relative to the respective time slot 1000 is set to represent the low and high load index. Therefore, there is no unit . In order to forecast electricity usage statistics based on the classification of the contract type classification, hierarchical classification, one type-specific sorting, classification and utilization peaks were classified by type of case working days (not include holidays from Tuesday to Friday) Sunday, Saturday, Monday, and was used. If the seasonal peaks by use of classification was based on the peak day occurred. 75,684 of these data, the industry has been created on the basis of the distribution of the Classifieds.



4.4 Adapting BESS

ESS installed capacity of 90% compared to the average operating efficiency is assumed to keep the amount of planning time and was discharged afford.

※ 8:00 a.m. to 7:00 p.m. discharge time Average price: 1256.5kW

※ (load values-day average value -1256.5) of the load values: 1736.4 kW

4.4 PROFITABILITY ANALYSIS

DOE's Sandia National Laboratories in the U.S. and launched in December 2012 ES-Select program, which was used as a database for information on battery storage system is as follows: Looking at the graph data 1kWh report if the price of $ 600 provided by the DOE, which shows the price of lithium ion in the price of industrial facilities and container type is determined by the middle of $ 400 was calculated assuming that the payback period. $ 400 per 1kw converted to the current exchange rate at the price of 440,000 won per 1kW to 2MW estimate of 880 million won in the case of the configuration was assumed to be costly.

CASE 1	Original A	ALT B	A - B
Base rate	657,047	630,290	26,757
Using amount	2,602,439	2,496,469	105,970
Reduce amount	14,152 dollars/ year		

CASE 2	Original A	ALT B	A - B
Base rate	657,047	616,941	40,106
Using amount	2,602,439	2,443,511	158,928
Reduce amount	20,783 dollars/ year		

CASE 3	Original A	ALT B	A - B
Base rate	657,047	604,431	52,616
Using amount	2,602,439	2,394,132	208,307
Reduce amount	26,972 dollars/ year		

CONCLUSION

Proceed in this study, the largest electric energy for the purpose of attention is focused on the investigation at this time and through the analysis of BESS actually have any effect on the building knowing about view. In fact, using the coefficient of relative configuration to look at energy usage and the actual usage is quite similar to the value estimate was confirmed. This allows the using of the monthly amount of electric energy consumption and in the process configuration. 3-4 hours in the case of ESS equipment to maximize the efficiency of the product can have an office building, the M -shaped energy load because it has a tendency of electric discharge by a particular time in a simple way, that there is a limit and then derives an analysis was . In the case of ESS equipment prices are falling faster in the state, but I think at this point, when the basis of a longer period of time had recovered. Future due to the rising cost of energy is electric charge realized the work is ongoing at the time BESS electricity rates will be rise building is an important element to be operated is obvious. In fact, users using BESS is to reduce the total amount of electrical energy , but not at the national level and a personal level to adjust the amount of load that can be used to reduce rates because they can serve as positive role in society generally we look forward to .

ABSTRACT

India is a growing to become world's third largest construction market by 2025. It is also accounting for 11% of India's GDP after agriculture in country. Construction material waste is generated during any new construction, renovation, demolition of buildings and infrastructure projects. Virgin material, after extraction, cannot be used in its original state for building construction. It undergoes processing, which involves consumption of energy in terms of manufacturing or finishing, transportation, etc. The construction waste is a by-product of construction process. Construction waste has embodied energy and also needs energy for its disposal in term of transfer to dumping sites, which affect the environment adversely.

The study on practices and procedures to reuse the waste on-site and maximize use of recycled material is important with a view to minimize possible usage of virgin material in construction process. For the purpose of this research, the construction process and practice of residential projects is considered. As 80% of the residential projects in India are executed through conventional construction process, it is imperative to observe and recommend appropriate methods of construction activity to optimize energy usage. Categorically large infrastructure project and large scale housing projects are not considered, since it has an alternative of pre-cast / prefab construction method. It is beyond the scope of this research

The research paper focuses on the energy involved in construction waste and deriving strategies for reusing and recycling of the same. It also identifies the causes of generation of construction waste along with the quantity of waste generated on-site at different stages of conventional construction process. This study will helps to encourage possible on-site practices and procedures to minimize the waste and to utilize the embodied energy involved in construction waste.

INTRODUCTION

India is growing to become the world's third largest construction market by 2025, as per a study by Global Construction Perspectives and Oxford Economics[i]. Today the construction industry is the second largest industry of the country after agriculture and it is accounting for 11% of India's GDP[ii]. The Indian economic environment and system and procedures would further enhance construction industry, as it provides the basic physical infrastructure for the nation as well as other industries.

In India, construction industry is not just the fastest growing industry but largest in terms of investment, volume of natural resources consumed, volume of materials and products manufactured, employment generated and environmental impacts, etc. Along with development, construction industry carries several challenges like emissions to air, land contamination, noise pollution, waste disposal and discharges to water[iii].

Due to huge consumption of construction materials, huge amount of construction waste is generated during construction.

The construction and operation of the built environment has been estimated to account for

- *12-16% of fresh water consumption;*
- *25% of wood harvested;*
- *30-40% of energy consumption;*
- *40% of virgin materials extracted;*
- *20-30% of greenhouse emissions;*
- *40% of the total waste stream of countries, 15-30% of which ends up in landfill sites;*
- *Up to 15% of purchased materials at jobsite ending up as waste.*[iv]

From above percentage, it is seen that the problem of landfill waste needs to be given top priority and has to be tackled as soon as possible, by finding strategic solutions to the problem. The construction waste dumped on landfill site, leads to soil pollution which affects soil fertility and also leads to sub-soil water pollution. Random dumping of these wastes leads to air pollution and degrades the air quality.

The construction waste involves energy in extraction, manufacturing process, transportation to construction site, construction process, finishing and transportation to the landfill sites. Construction industry needs to address this issue and re-examine their construction processes and practices in this regard.

METHODOLOGY

This paper explains the need of optimizing energy in construction projects and establishes the relationship of embodied energy in building material and the los of same through construction waste. It further discusses material losses on construction site in Indian context through having an adverse effect on embodied energy and correspondingly cost of the project.

This paper quantifies construction waste generated at different stages of construction process through case study method. The method adopted for understanding the market practices of waste handling is through interviewing professionals like Project management consultants, Architects, Civil Engineers, and Contractors working on the site. The outcome of the interview is tabulated in percentage of waste material with respect to the total quantity of specific material purchased on site for concerned project..

The study also quantifies the wastage through cost implication and also in terms of total embodied energy of the material. It then suggests strategies and recommendations for construction practices to reduce construction waste generation and also recomends procedures for reuse of construction waste material.

The research then identifies the quantum of the material that can be reused and reclyed on site and make practicing recommendations for the same. It further estimates the respective embodied energies that could be saved by implementing recommendations.

To conclude, it emphasizes on the need in selecting appropriate material including size.

NEED OF OPTIMIZING ENERGY IN CONSTRUCTION PROJECTS

Pune is one of the fastest growing metropolise in India. Most of the construction projects in Pune adopt conventional construction practices of in-situ construction. These practices are most suitable to the stakeholders in the industry as workers are easily available. The stakeholders try to incorporate advanced technologoies like design mix, pre-cast RCC members in the construction process. But they do not ensure no-wastage of materials on account of certain reasons. Unskilled labor is being one of the common reasons.

Construction waste occupies considerable storage space either on the road, river beds, hill slopes and land fill sites. The major environmental impacts caused by these wastes dumps have an impact on surrounding landscape. Since construction projects are going-on in most parts of the city including re-development projects in old limits of PMC and new projects in peripheral areas, increased amount of construction waste dumped randomly is evident.

As many of the landfill sites are already being exploited, the disposal of construction waste is an issue that has been seeking attention within both the public and private sectors in Pune city. The increasing costs of disposal gets reflected in project costs, as contractors have to incorporate anticipated disposal costs in their bid costing. Based on above fact, the emphasis is given for initiatives to reduce waste during construction activities to save environment and energy.

ENERGY USE IN BUILDING -

The energy usage in building is at four stages

1. Pre-construction stage – Energy in pre-construction stage:
   - To extract & process the raw materials, manufacture the building material
   - To transport the raw material from origin to manufacturing unit
   - To transport finished material and components from manufacturing unit to construction site
2. During construction stage - Energy used during construction process:
   - To operate machinery on job-site
   - For movement of vehicles on job-site to carry out construction process
   - Human energy on job-site

Architect Dharati Sote-Wankhade, Asst Professor in Dr. B. N. College of Architecture, Pune, Maharashtra, Mr. Dinesh Bhode, Controller of Examination, YCMOU, Nasik, Maharashtra, Architect Rahul Nawle and Architect Vaishali Angal, Professor in Dr. B. N. College of Architecture, Pune, Maharashtra

3. Post-construction stage - Energy used in collection, segregation and disposal of waste after construction process is over
- Transporting waste material to designated location to reuse or recycle or landfill site for disposal
- Energy used in reusing or recycling the waste
- Energy used in process of material reuse

4. Operation of building - Energy in operation is the energy used once the building is occupied.

The focus of this paper is on energy used during construction stage and at post-construction stage. The energy used to dispose of waste material is also considerable in complete construction process. The energy in disposing waste can be minimized to greater extent by reusing or recycling the waste material.

CONSTRUCTION WASTE -

Construction waste is produced in large quantity by infrastructure projects, renovation or demolition of structures, etc. There can also be non-hazardous by-products generated. Waste is generated during site preparation, material use, material damage during handling, material non-use, excess procurement and human error.

Components of Construction waste debris typically include concrete, sand, aggregate, plastic, flooring material, rubber sealants, glass, metals and metal alloys, wood and wood based products, masonry material etc. Land clearing debris, such as weeds, rocks is also included in construction waste.

ENERGY OF CONSTRUCTION MATERIAL – EMBODIED ENERGY

The embodied energy of a product includes the energy used to manufacture it all through the process of mining or harvesting the raw material, refining, processing, and various stages of transport, to the finished product at the factory gate. The process of analyzing and quantifying the energy associated in these steps is part of Life Cycle Assessment of the building. The scope of this research is limited to the estimation of embodied energy involved in construction waste during construction process. The Life Cycle Assessment of that specific building material is out of the scope of this paper.

Energy consumption for the transport of manufactured products from factory to the site can have a large role in the total energy calculations. The energy consumption on the building site includes mechanical and human energy required for mixing, transporting, placing, finishing and cleaning, etc. The amount of energy used on the building site has increased considerably in recent years as a result of increased mechanization and increased labor cost.

MATERIAL LOSSES AND WASTAGE ON CONSTRUCTION SITE

Every material has "loss factor", which describes how much of a particular material is typically lost during storage, transport and installation of final product.

The estimated material waste percentage differs as per construction material. The total amount of material purchased on the project site is as per this ´estimated quantity.

Table 1: Estimated wastage of construction material [v]

Sr. No.	Type of material	Estimated wastage
1	Cement	2 %
2	Sand	10 %
3	Aggregate	5 %
4	Concrete structural	2 %
5	Concrete binding (lean)	10 %
6	Reinforcement steel bars	3 %
7	Reinforcement steel mesh	10 %
8	PVC sheeting	15 %
9	Steel for windows	7 %
10	Timbering in trenches	5 %
11	Stone masonry	5 %
12	Marble lining	20 %
13	Wood for door frames	5-7.5 %
14	Wood for shutters	10 %
15	Wood for flooring / walling	5-10 %
16	Sheet roofing	2.1-2 %
17	Tile roofing	5 %
18	Floor railing	2-5 %
19	Wall tiling	3 %
20	Pigments (colors other than natural grey)	5 %
21	Paints	5 %

CASE STUDY OF PUNE - CONSTRUCTION WASTE GENERATED AT DIFFERENT STAGES OF CONSTRUCTION PROCESS

A residential project is studied to quantify the waste material generated on site. The study involves the quantification of waste in terms of embodied energy of material waste as well as in monetary terms.

Project details

- Project type – Residential project
- Location – Kondhwa, Pune
- Plot area – 22300 Sq. M.
- Built -up area – 12542.00 Sq. M.
- Number of buildings – 4 Numbers
- Number of Floors per building – Parking + 11 floors
- Ground coverage 4 buildings – 1688.43 Sq m (522.45 Sq m – 01 Tower
388.66 Sq m – 03 Towers)

Refer table 4 for details of construction material purchased, material used for construction of buildings and quantity of waste generated during the construction process of the case study. The maximum wastage of material that is observed is of sand i.e. 24.50%. Tiles have about 16.67% wastage, where as masonry, steel and aggregate has 11.82%, 8.62% and 10.81% respectively. The least wastage is observed of PVC conduits i.e. 7.70%.

This study deals with wastage of concrete and mortar material (residue) and not the raw material (cement, sand and aggregate) separately. However handling losses of waste materials are not considered.

It is observed that there is a difference in percentage of waste material from literature review vis-à-vis to the one on site (case study). In such case the percentage from literature review is considerd as reference (base line).

Along with this, the material cost is also calculated. For this the current market rate is studied from Pune city. The calculation shows that, the cost of construction waste is 11.60% as compare to the total amount of material purchased. This increases the project cost and so as selling cost of residential unit. Refer table - 5 for detail calculations.

The use of embodied energy involved in construction waste is calculated and analyzed. The wastage of steel, concrete, cement and conduits is very less as compare to sand and aggregate, but the embodied energy involved in this wastage is very high. Also the embodied energy involved in tile and masonry wastage is also considerable. Refer table - 6.

RESULT

The calculation for case study shows that, the amount of construction waste generated on construction site is @17.50% with respect to the total material purchased on site for the project. It involves @11.60% of the purchased material cost. Also the embodied energy of construction waste is @10.70 % of the purchased building material on project site.

The material waste generation in conventional construction process is huge in monetary as well in environmental impact terms. Thus, cost saving potential and the reduction in environmental impact due to construction waste should be taken into consideration by adopting suitable measures for construction waste reuse and recycle.

STRATEGY

The reduction of construction waste generation is possible by preparing Waste Management Plan and implementing it during and after construction process. Following are some of the recommended practices and procedures for reuse of construction waste that can be adopted in Indian scenario.

RECOMMENDED PRACTICES AND PROCEDURE FOR REUSE

- The specification and quality of construction material plays important role in waste generation during the construction process. It also affects the quantity of material consumed in the construction and finishing of building.
- To control the material usage in the construction process, the coordination among all those involved in the design and construction process from site selection to project completion is necessary. They should meet on regular basis and address the issues like dewatering operation from site clearing process and excavation for foundation, material delivery, its storage and use, solid waste management, vehicle and equipment management. Also, contractor and labor training should be directed in the complete construction process of the project.
- The quality work affects lot in quantity of material usage and the waste generated in the construction process. Ex. The leveled surface of concrete slab to avoid use of screed material for tiling, masonry work in plumb to avoid excess

plastering material.

- The formwork used in the concreting work affects the material wastage in construction process. The appropriate selection of formwork material i.e. instead of wooden formwork use of steel formwork, cause less wastage of concrete. The smooth finish of using steel formwork reduces the quantity of plastering mortar and finishes the surface.
- Waste from one activity can be used as raw material for another activity. Site management with parallel activities need to organize to reuse and so as to reduce the waste
- Mandatory segregation of waste material / debris on site to reduce mixed construction material waste
- Material storage
  i. Construct temporary material yard for separate storage of different materials. This reduces the mixing of materials stored on construction site.
  ii. Store the material on water tight raised platform. This will save material at lower level from mixing in soil to avoid land contamination
  iii. Cement bags stored directly on floor are vulnerable to contact with waster and moisture which leads to wastage of material to greater extent

Table 2: Recommended practices for reuse of construction material waste

S.N.	Waste material	Recommended practices for reuse of waste material on site
I	Block	To use as curbs to stop water runoff from garden area
		To construct pots for shrubs in terrace garden
ii	Tiles	To use tile adhesives for fixing tiles on leveled concrete slab, which avoids screed material use
		OR To use crush sand as bedding material for tiles
		To create Mosaic pattern in front of entrance door.
		To create pathways and walkway in the landscape area by using large and small pieces
		To create colorful fences around the flower beds
		To create reflective façade and terraces
iii	Concrete	To reuse concrete waste for temporary work or low-grade concrete work. This need parallel activities to plan on site.
		To recycle and use crushed concrete as aggregate for concrete
		To prepare lean concrete for PCC of compound wall, plinth filing, traffic movement
		To manufacturing paving blocks for lighter traffic movement
iv	Plastic	To recycle for re-manufacturing
v	Mortar	To use admixtures or plasticizers in mortar to reduce re-bounce waste
		To collect mortar at the end of day and pour in water to reuse it by crushing and adding cement for lower grade work of next day
		To collect mortar at the end of the day and mix in sand in proportion of 1:4. Use it for next construction work
vi	Packaging material	To collect and segregate the material at job-site. Send it for recycling. Do not store in contact with of water and moisture as it spoil the material
vii	Soil	To manufacture Stabilized mud blocks to be used in some other projects
		To use clay blocks for fencing around the trees or shrubs in landscape area of the project or in the terrace gardens
		Preserve top soil and do not mix with other construction waste. After the construction process is over, it can be used for landscape purpose on same or other site
viii	Brick	To use for paving in landscape
		To use as plinth filling material
		To construct curbs in landscape area to protect top soil run-off
		To construct Brick bat-coba for terraces and toilets
		To construct raised platform within building or project landscape area as a filling material
ix	Water	Save water by using gunny bag / cork bags for curing of concrete work
		Use curing compounds in concrete work
		Reduce water use by fixing water meter / water controller at pouring point into concrete mixer. This helps to maintain the quality of concrete.
		Collect cement mixed waste water through properly sloped trenches in sedimentation tank and reuse for construction work
x	Steel	To reuse 20mm diameter and above small length bars after coupler binding
		To send for recycle as it is recycled 100%
		To use sheering machine for steel cutting. This helps to reduce steel waste
xi	Paint	To use good quality paint to reduce consumption by quantity at source (minimum coats give perfect shade)
		To appoint skilled labor to use paint properly and reduce waste
		Good quality of plastering reduces the excess consumption of paint
xii	Rock from Excavation	To break with the help of crusher
		To use large size stone for construction of compound wall
		To reuse small size stones as aggregate
		PCC from crushed stone to reduce source material consumption

ESTIMATED QUANTITY OF REUSED MATERIAL AND EMBODIED ENERGY

The construction waste can be reused for various site development activities in the same project. The quantity of construction waste that can be reused for different construction stages is calculated and the embodied energy involved in reused waste material is calculated. Refer to table 4 and table 5. The cost of construction waste against the total material purchased for project is 11.60%. This is large investment in construction waste. See table 6 for detail calculations.

Refer to table - 7 for the detail calculations of quantity of construction waste reused on same site for other construction activities. The masonry material reuse is up to 80.57% in brick bat coba filling for terrace and dry terrace of the residential units and the filling below deck area.

The quantity of concrete material waste can be reused up to 93.00% in lower grade concrete for paving blocks of open parking, plinth filling of club house and bedding material below walkway in open space.

The waste steel bars of diameter 8mm, 10mm, 12mm can be used for chair bars, pins in beam. Also steel bars of length 4'0" to 6'0" can be used for toilet slab and consecutive footings. This can consume up to 10% of steel waste quantity.

The segregated and preserved mortar waste can be reused for paver block bedding material. This consumes 13.12% of the mortar waste quantity.

The tile waste can be reused up to 13.12% in parapet top, Flooring of staircase landing at terrace level, Mosaic flooring design in front of entrance door of residential units.

These findings reveal that, up to 23.25% of total construction waste can be reused on same project. This help to save the quantity of virgin material required in the site development work for the same project. The remaining waste material can be reused on the other project site as per requirement of the work.

ESTIMATED QUANTITY OF RECYCLED MATERIAL AND EMBODIED ENERGY

The construction waste material can be recycled at job-site. The estimated quantity of construction waste that can be recycled is identified and the embodied energy involved in it is calculated. This helps to save the energy required in the manufacturing process of virgin material.

Refer table - 8 for the detail calculations of quantity of construction waste recycled on job-site. The steel waste that remains after reusing on site can be sent for recycling. Since steel can be 100% recycled, it can be sent to manufacturing plant.

The PVC conduit waste that generates from plumbing and electrical waste should be collect and segregated carefully and sent to the job-site. This can help to recycle 85% of PVC conduits for manufacturing of new product.

WASTE MATERIALS AND 3R -

Today the construction industry is facing the issue of Management of huge construction waste. This research recommends the ways to reduce, reuse and recycle of construction waste in Indian context. Besides a clear understanding of the general concept of waste, it is helpful to use a classification of waste in different categories, in order to understand the wide range of possible corrective actions related to its prevention.[vi]

The different construction waste generated on site can be reduced, reused and recycled. Following are the possible measures towards waste minimization by implementing 3R concept to different waste materials on construction site.

Table 3: Construction waste and 3R

Sr N	Construction waste	Reduce	Reuse	Recycle
1	Soil		✓	
2	Cement	✓		

3	Sand	✓	✓	
4	Aggregate	✓	✓	
5	Concrete	✓	✓	✓
6	Steel	✓	✓	✓
7	Masonry	✓	✓	✓
8	Wood	✓	✓	
9	Tiles	✓	✓	
10	Pipes	✓		✓
11	Aluminum	✓	✓	✓
12	Glass	✓		✓
13	Plastic		✓	✓
	Packaging material			
14	• Paint cans	✓	✓	✓
	• Cardboard boxes	✓	✓	✓

Most construction waste materials can be reused and recycled. Often, it is just a matter of separating waste, either on-site or off-site and sending it to the relevant waste stream.

Dedicated storage spaces should be allocated for the collection and sorting of waste. These spaces should be easily accessible to workforce and be in close proximity to waste collection points. Bins or storage containers should be allocated to accommodate different waste streams including reusable waste, recyclable waste, rubbish (non-recyclable waste). It is important that storage areas are conveniently located within a construction site.

Also, the initiative and training to labor is as important aspect. The labor should be aware of the signage/graphics on the waste-bins and contribute in sending the waste to relevant material waste-bins.

CONCLUSION –

In the construction industry, the materials are transformed into elements; elements are transformed into components, components into systems and building. Thus they define the flow of materials and energy during construction and are responsible for flows of materials and energy from building sites.

The construction waste is generated from the stage of site preparation to building services like plumbing, electrification of the construction process. The various waste materials like concrete, mortar, tiles, brick, packaging material, water are generated from these stages.

The embodied energy involved in construction waste can be reused up to 35.23% and recycled up to 26.74% with the recommended practices and procedures in this research paper. An important procedure like placement of different containers to collect and store the segregated wastes should be adopted on site. The maximum reuse of waste material will minimize the resource consumption for the construction material manufacturing. This will also save the cost invested in construction material.

ACKNOWLEDGEMENT -

We wish to express our sincere thanks to Prof. Anurag Kashyap, Principle and Prof. Sujata Karve, HOD of M. Arch. (Environmental department) of Dr. B. N. College of Architecture for providing us opportunity to do our research on "Optimizing energy through on-site reuse and recycle construction waste in residential project – A Case Study of Pune". This research was put-up with efforts of many peoples.We would like to gratefully acknowledge the enthusiastic support to Ar. Ramesh Bhambhani for the technical discussion on this research topic. Our special thanks to Mr. A. D. Kale, Mr. Umesh Goel, Mr. P. V. Bhat, Mr. Vinod Mali, Mr. Ashok Retwade, Mr. Chandrashekhar Dhawan, Mr. Gawas for their kind co-operation of research work.

Use of Energy-efficient Materials and Sustainable Design Strategy for Large Sports Architecture in Beijing

Sun Yimin, Prof
[South China University of Technology, China, People's Republic of]

Xiao Hui, PhD candidate
[South China University of Technology, China, People's Republic of]

ABSTRACT

The sports facility typically requires large open spaces and thus falls into the category of energy-intensive public architecture. The level of energy consumption directly reflects the operation cost of a large sports facility. The future role of architecture design will be critical to help improve energy efficiency by designing sustainably. Through the study of the use of energy-efficient materials in the design and construction phase, this article analyses the trend of using new energy-efficient materials in large sports architecture in Beijing, and discusses the key factors and techniques for selection of those materials. The impact of using energy-efficient materials on large sports architecture on its daily operation is also discussed. Lastly, it proposes a sustainable strategy for large sports architecture, from architectural design to the selection of energy-efficient materials.

INTRODUCTION

As civilizations have evolved, so does the world's need for energy. The question of how to balance economic growth with care for the environment largely revolves around energy. Countries, including China, face the challenge of meeting rising energy needs in ways that are cost-efficient, sustainable and environmentally compatible. Buildings are becoming the heaviest consumers of natural resources in China. The area of public buildings accounts for about a third of the total civil buildings, but they contribute to more than 50% of the total building energy consumption. High-performance green buildings do not represent just an environmentalist vision. They represent opportunities to reduce energy and operation costs.

As typical large public buildings, sports stadium and arena are energy intensive. They have the greatest energy-saving potential and are playing a key role to achieve China's energy conservation goals. After successfully hosting the 2008 Beijing Olympics, China has entered into the "post-Olympic era" as hosting large sports events and building sports complex are becoming "new normal". In the process of design and construction, owners are paying more and more attention to their daily operational needs. Energy efficiency is an important factor which influences the operational costs of large sports buildings.

China's Ministry of Construction has issued a regulation on civil building energy conservation, which prescribes that "Civil building energy conservation refers to the activities of reducing building energy consumption, reasonable and efficient use of energy in the process of the civil buildings' planning, designing, construction and use". As building energy conservation is a systems engineering, this paper mainly discusses the energy conservation and the sustainable development strategy for large sports buildings, from the perspectives of architectural design and energy efficient materials selection.

INTENT AND OBJECTIVES OF APPLIED RESEARCH

This applied research is based on the case study of the 2008 Beijing Olympic Games' competition and training venues. As a delegate of the State General Administration of Sports, author B has been participated in the construction process of the two projects that are analyzed in this paper, and is able to apply the project data in the study. Through the study of the use of energy-efficient materials in the design and construction phase, this article analyses the trend of using new energy-efficient materials in large sports architecture in China, and discusses the key factors and techniques for selection of those materials. The impact of using energy-efficient materials on large sports architecture on its daily operation is also discussed. Lastly, it proposes a sustainable strategy for large sports architecture, from architectural design to selection of energy-efficient materials.

PROCESSES

Beijing Sports University Training Center (Hereinafter referred as BSU Training Center)

Project overview. Beijing Sports University National Team Training Base was invested by the State General Administration of Sports in preparation for the 2008 Olympic Games. It was constructed as a comprehensive training base with the function of national team training, scientific research and education. As a training venue for the national teams, the BSU Training Center's gross floor area is about 29,700 m^2, with a total investment of about 206.6 million Yuan. It is 288 meter long, 72 meter wide and 24 meter high, and is one of the largest comprehensive training venues in China. The ground part of the whole building area is divided into three structural units: the west wing for track and field training center (axis plane size is 72m by 128m); intermediate for taekwondo hall and comprehensive auxiliary facilities (axis plane size 72m by 90m); the east wing for rhythmic gymnastics and trampoline comprehensive training venue (axis plane size 72m by 72m).

Table 1 BSU Training Center's use of energy-efficient materials

Building Part	Material Type	Construction Practice	Measured K Value*	Local Standards
Outer wall	Decorative insulation bearing integrated block	310mm thick insulation block, with 80mm thick polystyrene board insulation layer	0.45W/m^2 • K	0.6W/m^2 • K
Curtain wall	Broken bridge aluminum alloy glass curtain wall	Broken bridge aluminum alloy, low-e insulating glass, 12mm thick air space,6+12A+6	2.3W/m^2 • K	3.0W/m^2 • K
Roof	Multi-functional composite metal roofing	Metal roofing, fills in a 100mm thick glass cotton	0.5W/m^2 • K	0.55W/m^2 • K

***Overall Heat Transfer Coefficient of Building Envelope**

Energy-efficient building materials selection. The architectural design follows the "public building energy conservation design standard" (Beijing local standard DBJ01-621-621), which requires an energy saving level of 65%. It applies the approach of green, energy efficient and environmental friendly in the architectural design and material selection, reasonability designs the thermal performance of building envelope, and reduces building energy consumption. Its shape coefficient of building, overall heat transfer coefficient of building envelope and other indexes meet or exceed the standard limit, which lays a foundation to reduce the cost of daily operations for the venue. The main parts that use energy-efficient building materials include:

1. Energy-saving outer wall. The outer wall heat preservation, to comply with the standard of 65% energy saving, uses decorative insulation bearing integrated block. The size of the block is 310x190x90mm, with an 80-mm thick thermal insulation material for polystyrene insulation board inside. To prevent cracking, workers were required to strictly follow the construction procedures. The block wall's overall heat transfer coefficient of building envelope (K value) was designed as 0.45 W/ (m^2 • K). After a review by the specialized institutions upon the completion of the construction, the actual heat transfer coefficient is confirmed to be less than 0.6 W/ (m^2 • K), which meets the requirements of the standard of 65% energy saving.

2. Energy-saving windows and doors (curtain wall). The venue's glass curtain wall airtight performance is designed as class Ⅲ. The low-e insulating glass with a radiation rate of less than 0.25 was selected. The hollow glass curtain wall is equipped with a broken bridge aluminum alloy, double-layer, 6mm thick low-e glass and 12mm thick air space. All south to glass windows and glass curtain wall were installed with the set of infrared remote control electric sunshade inside. K value of the glass curtain wall is 2.3 W/ (m^2 • K).

3. Energy-saving roofing. The roofing of the venue uses the compound metal insulation board, filled with 100mm thick centrifugal glass cotton. The metal roofing system consists of a magnesium aluminum manganese alloy roof board, insulation,

lining layer, purlin and a sound-absorbing, galvanized steel base plate. K value of the metal roofing is 0.5 W/ (m^2 • K).

Beijing Shooting Range Hall

Project overview. Beijing Shooting Range Hall is the 2008 Olympic Games' shooting competition venue. It consists of a 10m air rifle hall, a 25m pistol pavilion, a 50m target pavilion, training and game rooms, technology rooms and supporting services, with a comprehensive function of training and competition. It serves as the national shooting team's training venue and a major competition venue. The gross floor area of the venue is 45,645 m^2, with a seating capacity of 9,000 audiences. The main structure of the venue is frame-shear wall structure, using the large-span space steel pipe rack and truss roof system.

Figure 2 Photo-realistic of Beijing Shooting Range Hall
Source: http://lvyou.baidu.com/beijingshejiguan

Energy-efficient building materials selection. The architectural design performs the "public building energy conservation design standard" (Beijing local standard DBJ01-621-621), which requires an energy saving level of 65%. The venue design emphasizes the building functions, convenience & economy of use, leveraging the ecological building technology which is mature, reliable, and efficient. Through the use of architectural structure, detailed and appropriate building technology and materials, it enhances the overall quality of the construction. With the goal of being a green building, the venue used precast concrete heat preservation sound insulation wall panels, ecotype double breathing curtain wall, multi-functional composite metal roofing and other energy-saving new technologies. By using these typical energy-saving materials, it can effectively reduce the heat transfer coefficient of the building, and improve the overall thermal insulation performance.

1. Energy-saving outer wall. As a large sports facility, the Beijing Shooting Range Hall pursuits for an architectural style of simple natural atmosphere, as its facade emphasizes on large scale frame and deep seam decorative texture. It uses the outer walls of precast concrete heat preservation sound insulation wall panels, which are good for exterior wall thermal insulation, sound insulation, heat insulation, components and exterior decoration. As regards the construction technology, the first structure pendant was set aside for building structure, pasting 30mm thick extruded polystyrene insulation board on retaining wall surface, and hanging precast concrete wall panels outside. Hanging panels with insulation layer formed about 40mm air between the layers. The air layer is advantageous to the wall heat preservation and sound insulation, which greatly reduces the influence of indoor shooting training and competition to the external environment. At the same time, use of precast concrete heat preservation sound insulation wall panels can save the operational cost without more maintenance investment. By using the energy-saving outer wall system, the exterior wall heat transfer coefficient of the venue is greatly reduced. K value of the venue is significantly lower than the standard requirement of 0.6 W/ (m^2 • K).

2. Energy-saving windows and doors (curtain wall). When the venue was designed, it proposed a creative design of Ecotype double breathing curtain wall, considering the special requirements of sound insulation, viewing and energy saving. The curtain wall system is an externally circulating double curtain wall, with auxiliary external sunshade measures and intelligent control system, combining architectural shading, ventilation, ventilation function into an organic system. It also improves the construction technology for physical comfort. The inner glass wall uses 6 + 12A + 6 toughened hollow low-e glasses, and the outer is with 12-mm toughened glasses. The glass size is 1400 mm x 2500 mm. Calculation shows the ecological breathing curtain wall heat transfer coefficient has decreased to 1.3-1.5 W/m^2.K, which is much better than the public building energy efficiency standards and greatly reduces building energy consumption.

3. Energy-saving roofing. The Beijing Shooting Range Hall chose bem aluminum roofing system. Its metal roofing uses 0.9-mm thick aluminum manganese magnesium alloy plate, featured with light weight, high hardness and flexibility, corrosion resistant and maintenance-free. Roof construction bottom-up is ranged by: plate, aluminum foil, insulation cotton, purlin bracket, purlin, roofing and roof panel. Fire prevention, heat preservation cotton was adopted to achieve preferable centrifugal glass cotton insulation performance, and the thickness reaches 150 mm. By adding a layer at the bottom of the glass cotton insulation moisture-proof aluminum plus fascia, the roofing heat preservation performance is greatly improved. K value of the metal roofing is decreased to about 0.38 W/m^2, K.

Table 2 Beijing Shooting Range Hall's using of energy-efficient materials

Building Part	Material Type	Construction Practice	Measured K Value*	Local Standards
Outer wall	Precast concrete heat preservation sound insulation wall panels	Building structure reserve structure is hanged, retaining wall surface paste 30 mm thick extruded polystyrene insulation board, dry hanging outside of precast concrete wall panels, hangs panels with insulation layer formed between about 40mm air between the layers	<0.6W/m^2 • K	0.6W/m^2 • K
Curtain wall	Ecotype double breathing curtain wall	Inner wall of glass use 6 + 12A + 6 toughened hollow low-e glass, the outer with 12mm toughened glass	1.3-1.5W/m^2 • K	3.0W/m^2 • K
Roof	Multi-functional composite metal roofing	Metal roofing uses double metal plate, two layer board adopted the good fireproof and heat insulation performance between centrifugal glass wool, thickness of 150mm	0.38W/m^2 • K	0.55W/m^2 • K

***Overall Heat Transfer Coefficient of Building Envelope**

Survey of energy consumption in daily operations for the two venues

As a comprehensive training venue project, the Beijing sports university training center was completed by the end of 2007 in preparation for the Olympic Games in 2008.The Beijing Shooting Range Hall, which was completed in 2007, hosted the test event to stage the games in August 2007 and the Olympic Games official competition in 2008. The two venues are subordinate to the State Sport General Administration. The owners are respectively the Beijing Sports University and the Archery Shooting Sports Management Center under the State General Administration of Sports. After the 2008 Olympic Games, the two owners are responsible for the daily operations of the facilities. In this paper, the daily operational energy consumption levels of the two venues in 2008-2010 were investigated and analyzed. The comparative datas are from a research on quota of operation energy consumption for venues and accessory facilities by the State General Administration of Sports. The energy consumption values are set in accordance with the unified running time, which is 8 hours per day, 6 days per week(according to the training character of sports teams),and 12 months per year.

1. Electric power energy consumption spending

BSU Training Center's power energy consumption in 2008-2010 is 2643,300 kWh, 2651,913 kWh, and 2613,600 kWh respectively. The average annual electricity consumption of the venue is about 2.64 million kWh. Beijing Shooting Range Hall's power energy consumption in 2008-2010 is 2181,470 kWh, 2226,619 kWh and 2224,712 kWh respectively. The average annual electricity consumption of the venue is about 2.21 million kWh.

2. Energy consumption analysis

Training venues' energy consumption level is higher than the competition venues, due to the higher proportion of large space, and less accessory occupancy. Beijing Shooting Range Hall's annual power consumption in construction square meters is 48.4 kWh/m^2•a. BSU Training Center's annual power consumption in construction square meters is 88.9 kWh/m^2•a. Beijing Shooting Range Hall's annual heat/gas energy consumption in construction square meters is 21.3 m^3 / m^2•a. BSU Training Center's annual heat/gas energy consumption in construction square meters is 105.4 m^3 / m^2•a.

3. Comparison with the similar venues of the State General Administration of Sports

To analyze the energy saving performance, we choose some similar venues for comparison, which are subordinate to the

State Sport General Administration. The sample venues were all newly built or renovated for the 2008 Beijing Olympics, with the gross floor area of more than 20,000 m^2, and the highest ceiling height of more than 16 meters. We take the whole architecture as the research object, including the arena, stands and accessory functional rooms. The electric power energy consumption of BSU Training Center and Beijing Shooting Range Hall, are in the middle range of the group of similar venues, and both are lower than the quota standard set by the State Sport General Administration.

Table 3 Energy consumption comparison with the similar venues of the State General Administration of Sports (Excluding the heating energy consumption)

Item	Project Name	Average Electric power energy consumption (kWh / m^2•a)	Gross floor area(m^2)
Training venue (ceiling height more than 16 meters)	BSU Training Center	88.9	29700
	Comprehensive Training Venue of National Olympic Sports Center	69.6	27000
Competition venue (ceiling height more than 16 meters)	Beijing Shooting Range Hall	48.4	45645
	Laoshan Cycling Velodrome	102.0	38000
	National Olympic Sports Center Gymnasium	40.1	32410

From another perspective, we compare the two venues with the Sports and Cultural Center in Shenzhen Overseas Chinese Town, which is among the first buildings that have been certified as the National Three-Star Green Building. The compared building was built in Oct, 2008, with a gross floor area of 5130 m^2, and building height of 15 meters. The annual operation energy consumption intensity of the building is 50.35 kWh/(m^2 • a). Although the building scale of BSU Training Center and Beijing Shooting Range Hall is much larger than this green building, their operation energy consumption intensity is close.

4．Comparison with Chinese large public buildings' current energy consumption

According to a research of Building Energy Research Center of Tsinghua University in 2009, the Chinese large public buildings' current energy consumption are 70-300kWh/(m^2 • a) (excluding the heating energy consumption). The researched large public buildings are central air conditioning and having a building area of more than 20,000 m^2.

The Building Energy Research Center of Tsinghua University also suggested a reference energy consumption index for new-built large public buildings in Beijing in 2010. The index for public office buildings is 72 kWh/(m^2 • a). The index for business office buildings is 105 kWh/(m^2 • a). The index for hotels is 141 kWh/(m^2 • a). The index for large shopping mall is 210 kWh/(m^2 • a). However, they didn't give a suggestion for large sports buildings.

Compared with the above existing data, the energy consumption level of Beijing Shooting Range Hall and BSU training center is significantly lower than that of most of the large public buildings.

OUTCOMES

New trend in the application of energy-efficient building materials

Energy-efficient building materials refer to the building materials with low energy consumption in daily operations and in the process of building, by changing the nature of the materials to achieve the goal of building energy efficiency. The significance of applying energy-efficient materials is that while meeting the architectural space or the thermal environment of thermal equipment, it can help save the energy to a great extent. China is paying an increasing attention to the building energy efficiency and the implementation of corresponding energy saving standards and norms, and the rapid development of building energy saving materials. From the case study of Beijing Shooting Range Hall and BSU Training Center, we can find that the evolvement of applying a single energy saving material to the development of multifunctional composite materials and an energy saving system is becoming a new trend in the application of energy-saving materials. For example, the BSU Training Center's decorative insulation bearing integrated block, Beijing Shooting Range Hall's precast concrete heat preservation sound insulation wall panels etc, are all applying the composite materials to form a comprehensive system of energy conservation.

Key parts and techniques for selection of energy-efficient materials

For large sports architecture, the thermal performance of building surrounding structure is very important to the building's energy efficiency performance. According to the spatial characteristics of the large-scale sports building, the key parts of energy conservation and material selection are outer walls, doors and windows (curtain wall) and roofs. Key techniques are the integrated system structure, processing hot bridge and cold bridge, through improving the structure of heat preservation and insulation system to achieve good energy saving performance.

The energy saving performance

Both Beijing Shooting Range Hall and BSU Training Center are large sports buildings. Beijing Shooting Range Hall has a total length of 420 meters, while Beijing Sports University training center has a total length of 288 meters. Both venues are more than 20-meter high. Through using energy-efficient architectural design and materials in the key parts, the two venues achieved good energy saving performance, significantly lower than the energy consumption level of most of the large public buildings in Beijing. The venues are the models of the green Olympic buildings.

INFERENCES AND CONCLUSION

Sustainable architecture is a future trend. The energy conservation potential for large sports buildings is tremendous, so they should be guided under the energy efficient and environmentally friendly sustainable development strategy. The key is to implement sustainable architectural design methods and to select energy-efficient materials in the process of construction.

Sustainable building design

We should start the research from the angle of ecological sustainability, and achieve the goal of sports building energy saving, water saving and material saving design strategy, through the use of appropriate technology. Considering the domestic situations, we should work out a strategy of reducing total life cycle cost from three aspects: the initial cost, maintenance cost and update cost control. Based on principles of intensive construction, we can explore sports building design strategy of low cost and low loss which addresses the current situation of China.

Energy conservation and material selection

The main energy conservation goal of large sports building is to consume as less energy and resources as possible, in the meanwhile minimizing the impact on environment and ecology, and providing the users with a healthy and comfortable building environment. Choosing energy-saving materials in the process of design and construction, and implementing building energy efficiency standards, is an important approach to realize the energy conservation goals and promote the sustainable development concept of the large sports building. Through the reasonable design and selection of energy-efficient materials, we can gain great energy efficient performance in the long run in exchange of a smaller building cost increase at present.

Performance of Phase Change Materials for Cooling of Buildings in Mild Climates

Bouguerra E.H., PhD
Mechanical Department
Blida I university, Algeria
EhBouguerra@yahoo.fr

Retiel N., PhD
LMNEPM
University of Mostaganem

ABSTR ACT

The effect of phase change material (PCM) integration in buildings is investigated in mild climates for the entirety of the hot season. The incorporation of PCMs in building materials is particularly interesting because it allows for the thermal storage to become a part of the building structure while being completely passive. Simulations in a typical single-family home are carried out, and the effect of incorporating PCMs in different building components is analyzed. Results show an important reduction in cooling energy.

1- INTRODUCTION

World electricity consumption is expected to double by 2025, increasing at a significant rate of 3.5 % per year. Furthermore, the demand for thermal comfort in both domestic and commercial buildings is currently rising. The additional energy demand significantly contributes to the increasing consumption with a peak demand in mild and hot climates. However, any action must start by reducing the level of energy consumption or at least delaying the peak demand.

To shift the peak energy demand (ideally few hours), the thermal mass of buildings can be used to store energy and lessen indoor temperature fluctuations. Nevertheless, the requirements of a thermally massive building often conflict with cost or aesthetics that require buildings to be increasingly lightweight. Incorporating phase change materials (PCMs) into buildings is a way to artificially increase the thermal mass of lightweight structures (Zhang et al, 2007). Heat storage can either take sensible or latent forms. Sensible storage is accomplished by increasing the temperature of the material, whereas latent heat storage is accomplished by changing the physical state of the material. To store the same quantity of energy, a smaller amount of material is required for latent storage. For example, a common building material, such as concrete can store about 1 kJ/kg when subject to a temperature increase of 1°C, whereas a PCM, such as calcium chloride hexahydrate can store/release up to 193 kJ/kg on complete phase transition (Kenneth and Gates, 2000). This huge increase of thermal storage capacity for PCMs and their almost isothermal discharge could be used to stabilize ambient temperatures inside buildings.

Currently, the available commercial micro-encapsulated PCMs are made with paraffin waxes embedded within small polymer spheres of about 10-20 μm in diameter. When in powder form, PCMs can be mixed directly into the building material or internal wallboard without risking leakage. The additional latent heat capacity for the distributed PCM increases the overall effective heat capacity when compared with sensible storage alone (Khudhair and Farid, 2004). The main advantage of setting a PCM in wallboards and incorporating it into the internal side of the external envelope of a building is to have a large surface in contact with the indoor air.

Recently, incorporating phase change materials (PCMs) in building materials to reduce the cooling needs has been investigated in many studies. An extensive literature review on micro encapsulated PCMs and the application in buildings can be found in (Osterman et al, 2012) or (Zhao and Zhang, 2011). However, these studies mainly address lightweight or reduced scale constructions (laboratory scale testing, (Tardieu et al, 2011). Therefore, the obtained results cannot be generalized and are inconclusive regarding the benefits in real buildings and climates. Indeed, the experience conditions for the reduced scale generally lead to a large day/night temperature variation, which allows the PCMs to swing widely around the melting temperature. In this case, charge and discharge cycles are fully accomplished, and in turn, PCMs are in their optimum working mode. However, when simulating a long period (all the hot season for example), it is the average values that must be considered. A PCM can perform badly on a particular day, but might still perform well on average for the whole season.

With this work, our aim is to see how PCMs can reduce thermal loads in real buildings and how they can decrease fluctuation of indoor temperature to improve summer thermal comfort. Additionally, we will try to see if a unique optimum switch temperature exists and what parameters influence this temperature.

2- MATHEMATICAL MODEL

For the mathematical modeling, a nodal method was used. With nodal methods, a system is decomposed into isothermal (but not necessarily elementary) volumes. Each volume Vi is represented by a node with calorific capacity $C_i=\rho_i Cp_i V_i$. The heat exchange of a node with its neighbors is represented by thermal conductances (opposite to thermal resistances) characterizing different modes of heat transfer (conductive, convective, radiative and “fluid”). The energy conservation equation at node i connected to its neighboring nodes j and with a heat source $Q_i(t)$ is as follows:

$$C_i T'_i = C_i \frac{dT_i}{dt} = \sum_i G^c_{ij}\left(T_j - T_i\right) + \sum_k G^r_{ik}\left(T_k - T_i\right) + Q_i(t) \qquad (1)$$

G^c_{ij} and G^r_{ik} are conductive (or convective) coupling conductance and radiative conductance, respectively. When applied to all nodes, the energy conservation equation leads to a set of nonlinear, yet ordinary algebraic-differential equations. A dynamic solver is then used for the transient resolution. This type of method provides a very powerful tool for modeling complex systems with heterogeneous interactions, such as a building, and the precision is within the limit of validity of the isothermal assumption of the chosen nodes. In our case, the main advantage of those methods is the ability to consider the wallboard as an isothermal single node and then not necessarily solve the melting front position. The modeling of latent heat change use only its effective capacity C_{ef} , which is temperature dependant. It is treated as non-linear, such as others temperature dependant physical properties or conductances (natural convection or radiation for example). The actual solvers are robust and can deal with the very sharp evolution of C_{ef}.

The encapsulated PCMs are particularly candidates for this type of modeling because they are randomly mixed with gypsum to form a homogeneous material. The heat capacity is the sum of the capacities of the constituents (sensible and latent) as shown by (Shukla et al, 2012) and the density is the weighted average of densities.

3- PCM CHARACTERIZATION

Among key parameters for PCM simulation, thermal properties such as switch temperature and the enthalpy variation with temperature of are of primary importance. From the enthalpy variation h=f(T), which can be determined by several methods, such as Differential Scanning Calorimetry (DSC) or T-history, the effective capacity, C_{ef}=f(T) is a follows:

$$C_{ef} = \frac{\partial h(T)}{\partial T} \tag{2}$$

Because the model takes into account the phase change by the variation of the heat capacity during the phase transition, it is necessary to know its explicit variation versus temperature. There are several representations for this variation of C_{ef}. (Feustel, 1995) gave a simplified representation with an exponential symmetrical shape:

$$C_{ef} = C_{sl} + \frac{\Delta H}{2} \frac{2\beta / \tau}{Cosh^2\left[\frac{2\beta}{\tau}(T - T_m)\right]} \tag{3}$$

Where C_{sl} is the liquid phase heat capacity; ΔH the fusion latent enthalpy and T_m is the melting temperature (or switch temperature), β is a shape parameter and 2τ is a range where 99% of the phase change occurs (melting or freezing). The solid-solid peak transition is neglected because the temperature is not relevant for the wall's operating temperature. The representation is also using equal capacity values for liquid and solid phases. No hysteresis was also assumed between melting and freezing, which is generally the case with organic PCMs. In fact, in our calculations, a slight hysteresis (a shift of approximately 1°C) had practically no effect on long-term simulation if the switch temperatures are close to the optimum values.

Different values for the conductivity of gypsum with PCMs are found in the literature ranging from 0.15 W/mK to 0.6 W/mK mainly because different conductivities of the gypsum matrix are reported. A conductivity of 0.3 W/mK is considered for this work and the change of phase of the PCM do not have a substantial influence on thermal conductivity of the wallboard (Jaworski and Abeid, 2011).

4- THE CASE STUDY MODEL

Among numerous factors that influence energy consumption and performance of buildings with PCM integration, the following main parameters are identified:

- Local construction systems (envelope and windows).
- Local climate: solar irradiation and ambient outdoor temperature.
- Internal loads: the personal occupancy and electrical appliances (lights, TV, computers, etc.).

The case study involves a typical residential single-family house with an area of approximately 104 m^2 area, two bedrooms, one living room, one kitchen, one bathroom and one storage room.

Two windows (simple glass U=4.4 W/m^{2}K) are located in the north and south walls and the window-wall ratio (WWR) is approximately 12% (see figure 1 for the sketch). The constructive system is typical of the Mediterranean countries with a relatively heavy envelope (solid concrete end-terrace roof and measonery brick walls). Windows are shaded is by roof eaves and shutters (shading factor fs=0.5) in the summertime and the solar absorptivity is assumed 0.5 for the roof and the walls.

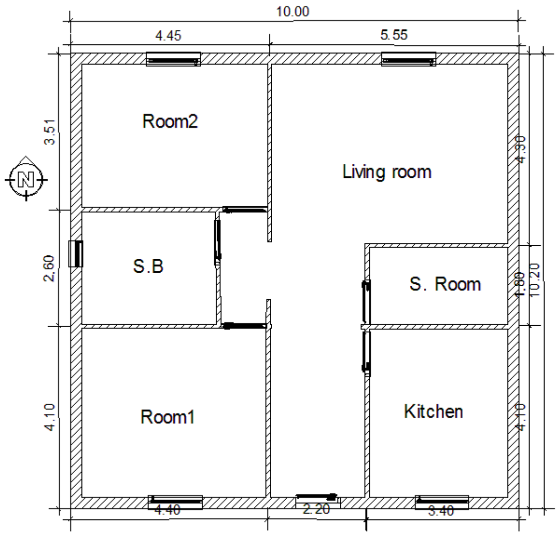

Fig 1. Sketch of the building model.

Exterior walls are traditional double brick walls with a 5 cm air gap (see table 1 for thermal characteristics of building components). The levels of insulation seem to be lower compared to those in continental climates, but they are sufficient for the Mediterranean region. PCM (when being present) of varied switch temperature between 24°C and 32°C is embedded in the wallboard of gypsum plaster of 15 mm nominal thickness. They contain between 0% (no PCM) and 30% mass fraction of encapsulated paraffin and are set into the internal face of the walls or the ceiling.

Table 1. Thermal characteristics of the building components.

	Roof	**Ext. Wall**	**Floor**	**Glass**
U-value [W/m^{2}K]	1.26	1.23	2.41	4.40

The study is carried out for the city of Djelfa, Algeria a typical Mediterranean city with a sub-continental climate: a mild-warm climate and relatively hot and dry summer. When the indoor temperature exceeds 26°C, cooling is activated and split system room air conditioners with 100 W/m^2 power are used. Thermal loads for occupancy and appliances are omitted to obtain a non perturbed comparison for PCM efficiency. For the same reason, only the absolute indoor temperature (and not operative or adaptive temperatures) is considered. The internal convection coefficient is difficult to determine because deviations of more than 100% can be found in the literature (David et al 2011). In this study, h=8.3 W/m^{2}C is used for vertical walls (according to ASHRAE recommendations, Diaconu and Cruceru, 2010) and h=3 W/m^{2}C for ceilings (stratified hot air on top) as average values for combined transfer coefficients (convective and radiative).

5- RESULTS AND DISCUSSION

The year round cooling performances of a PCM are evaluated. However, only the summer period is considered, i.e., June, July, August and September (the period from June 1st to September 30 is also generally the period where the differentiated electricity price for on peak and off-peak period exist in many countries). Two very simple indicators are used.

The first indicator is for a passive house (free cooling without air conditioning) with a "discomfort index" I_{sum} (Zhang et al 2007, modified by scaling it for the considered period):

$$I_{sum} = \frac{\int_{season} (T_{in} - T_{set})\, dt}{Season} \qquad \text{when } T_{in} > T_{set} \qquad (4)$$

This indicator shows how long (and how much higher) the indoor temperature is above the comfort temperature, which is assumed to be 26°C (overheating). The second indicator is for an air-conditioned house and shows the primary energy demand Q_c, or the quantity of primary energy that needs to be removed from the indoor building by an active cooling system to confine the indoor air temperature to a maximum of T_{set}=26°C.

$$Q_c = \int_{season} q_c dt \qquad (5)$$

Figure 2a shows the indoor temperature with a 30% PCM fraction weight and T_m=25°C and figure 2b shows T_m=27°C (ΔH=160 kJ/kg). From those figures, we can see that for T_m=25°C, the PCM performs well early in the hot season in June and in late September, but less so in the middle of the hot season (the hottest days). With T_m=27°C, the PCM seems to work mainly in the middle of the hot season (July and August). The adjustment of the switch temperature permits to control of which days of the hot season are concerned by PCM action.

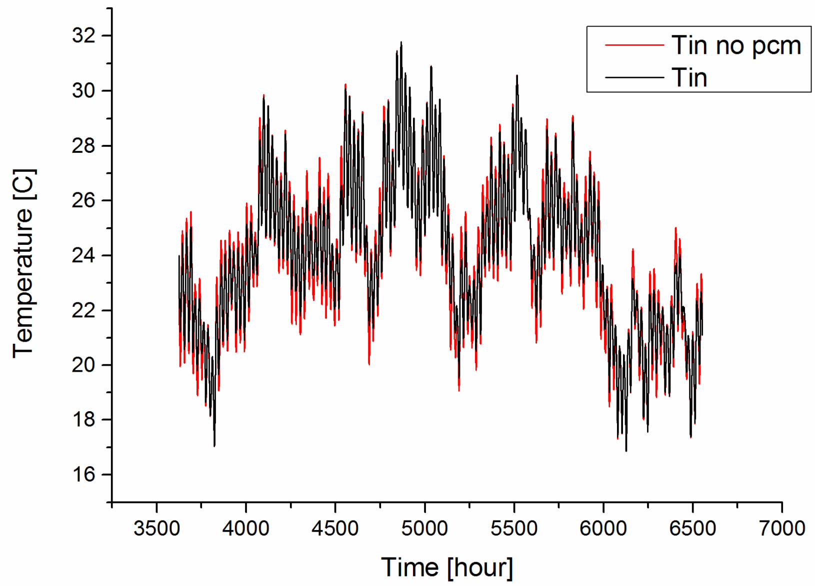

Fig 2a. Evolution of the indoor temperature without and with PCM, T_m=25°C.

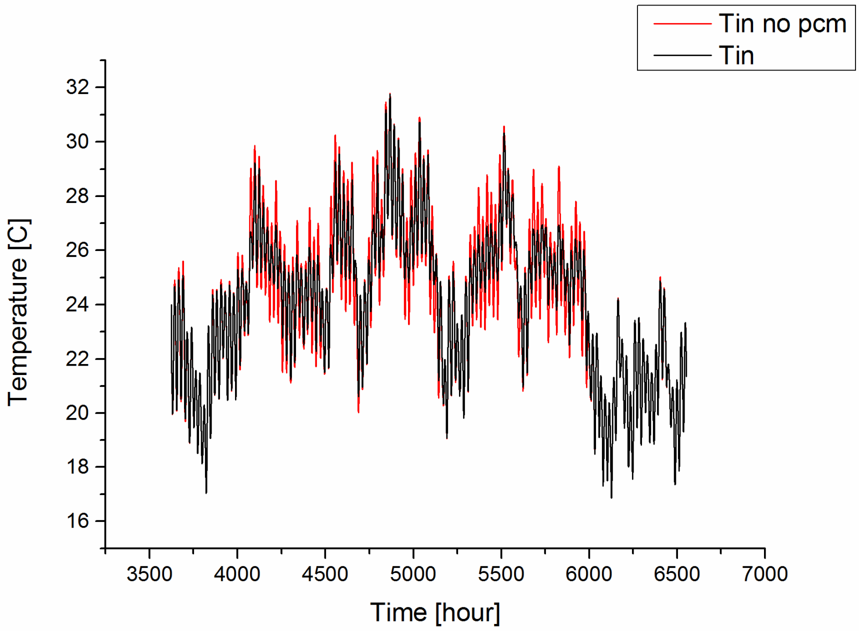

Fig 2b. Evolution of the indoor temperature without and with PCM, T_m=27°C.

Table 2 shows the discomfort index Isum and the cooling load Q_c for a PCM set on the internal face of walls and the ceiling for different switch temperatures and for a PCM fraction weight of 30% and with T_{set}=26°C. It is clear with those two indicators that the optimum switch temperature is between 26 and 27°C. However, a switch temperature close to this range would provide slightly different results. The maximum reduction on cold demand with the incorporation of PCMs is about 20% which is in the average of results found by the others studies.

Table 2. Discomfort index and cooling load variation with switch temperature T_m (W_t=30%, τ=3)

	No PCM	T_m=25°C	T_m=26°C	T_m=26.5°C	T_m=27°C	T_m=28°C	T_m=29°C
I_{sum}	0.642	0.557	0.524	0.514	0.508	0.514	0.530
Q_c [kWh]	1384.01	1171.36	1111.24	1106.50	1118.07	1160.02	1175.85

It is interesting to see if this optimum switch temperature is the same for both components (walls and ceiling). Table 3 shows the two indicators with PCM only set on the walls and Table 4 shows those with PCM only set on the ceiling (internal face). The results show that the optimum switch temperature is approximately 26°C for the walls and approximately 31°C for the ceiling. This is because the walls and the roof do not receive the same amount of solar irradiation and consequently, do not operate at the same temperature.

Table 3. Discomfort index and cooling load variation with switch temperature T_m PCM set on the walls (W_t=30%, τ=3)

	No PCM	T_m=25°C	T_m=26°C	T_m=27°C	T_m=28°C
I_{sum}	0.642	0.560	0.530	0.529	0.555
Q_c [kWh]	1384.01	1178.17	1127.06	1172.42	1282.25

Table 4. Discomfort index and cooling load variation with switch temperature T_m PCM set on the ceiling (W_t=30%, τ=3)

	No PCM	T_m=28°C	T_m=29°C	T_m=30°C	T_m=31°C	T_m=32°C
I_{sum}	0.642	0.591	0.571	0.556	0.553	0.562
Q_c[kWh]	1384.01	1258.00	1201.59	1161.31	1154.00	1178.75

Note that even if the areas (and then the PCM quantities used) for the ceiling and the walls are equivalent (102 m^2 and 113m^2, respectively) and the received irradiation is different, the PCM perform in the same way (16.5% and 18.5% in reduction of the cooling demand, respectively). In fact, the ceiling receives more solar irradiation than external walls but has in revenge a weak convection heat transfer coefficient compared to the walls.

6- CONCLUSION

The incorporation of encapsulated PCMs in building materials such as gypsum wallboards was investigated for the entirety of the hot season to reduce cooling energy or enhance thermal comfort. The PCMs are found to perform well a reduction of approximately 20% for cooling energy. This PCMs performance is realized even in mild climates characterized by low day/night temperature swings, which make night time ventilation less efficient for discharging the PCM. Anyway, the reduction of the cooling energy is obtained with relative large quantity of PCM. A local economic efficiency analysis must confirm the process profitability.

The PCMs have better performance on surfaces that undergo the widest temperature variation. Incorporating PCMs on the ceiling give the best compromise gain/cost and is relatively easy to realize even in existing houses. This shows their potential use for refurbishment of actual buildings which is the weak point of all energy conservation policies.

Exploring New Methods of Constructing Houses with Sustainable Materials in Rural Bangladesh

Rob, Fawaz, MA, IDSA
North South University
fawazrob@northsouth.edu

ABSTRACT

The paper investigates methods of house construction using organic materials in the rural areas of Bangladesh. Historically, people of Bengal have built their houses with natural and sustainable materials like mud, thatch and bamboo. However, the sustainable and vernacular tradition of homesteads went through major transition in the last century and the natural materials have been replaced with non-organic and energy inefficient materials like CI sheet, oven-baked brick and cement. Moreover, wood, a very scarce material in Bangladesh is widely used for doors, windows and roof structure. Research shows that these materials contribute to pollution, deforestation and depletion of fertile top soil. To tackle these challenges, different materials and techniques were implemented in building houses in the northern Bangladesh. The paper discusses the new method which eliminates CI sheet, wood and baked brick from construction process and instead implements compressed earth blocks, jute based tin roof and processed bamboo. Some of these cost effective construction techniques have already been practiced over the years in the rural areas of Brazil, Columbia and India with positive impact. This paper through a series of examples, discusses these new construction methods implemented in rural Bangladesh which directly contributes to reducing carbon emission and decreasing of deforestation.

INTRODUCTION

The paper discusses new methods and materials of constructing rural houses using compressed earth block (CEB), Jute Composite Tin (JCT) and bamboo. A two storied clinic was built using the new methods in the remote area of Bangladesh. Using this clinic as a case study, the paper discusses techniques, research findings and outcome of the construction method.

There are over hundred million people inhibiting rural areas of Bangladesh. Most of the country is low lying flat land with numerous rivers crisscrossing the plane. Historically, people of Bengal delta have built houses with natural and sustainable materials like mud, thatch and bamboo. The process has changed significantly over the last half a century and now the major materials used to build houses are CI sheet, Kiln baked brick, cement and wood. At present over 8000 brick factories produce nearly eight million tons of carbon emission every year. Corrugated iron industry adds another six million tons of CO_2 in the air. Generally the house owners, local masons and small contractors play significant role in the construction process in the rural areas. For most of them material choices are scarce and expensive. A corrugated iron sheet house has little or no insulation and contributes to poor housing situation. The new method of construction aims to handle these challenges.

INTENT AND OBJECTIVES OF APPLIED RESEARCH:

The objective of the project was to acquire knowledge in the new construction method and to find out if the new construction method can be socially and economically viable for the rural architecture of Bangladesh. Instead of using kiln fried bricks, the intent was to use CEB and measure its impact. Moreover, Jute Composite Tin (JCT) was used instead of Corrugated Iron sheet to measure the technical and environmental impact. Cured bamboo was used in constructing the second floor to minimize the static load. Also, implementing cross bracing and other construction technique, the longevity and the strength of the building was measured. Finally, the environmental impact of earth, jute and bamboo as construction materials were observed compared to current models.

Figure 1 *A clinic in rural Bangladesh built with Earth, Bamboo and Jute*

Fawaz Rob is a senior lecturer in the Department of Architecture at North South University, Dhaka, Bangladesh. He is also a consultant for the Government of Bangladesh, SAFE and Habitat for Humanity.

CONSTRUCTION APPROACH:

COMPRESSED EARTH BLOCKS (CEB)

A small mobile unit of CEB machine was installed on site to produce the bricks. The machine was locally produced from free source design material available on the internet. The machine produced on an average 1000 bricks per day. The main ingredients for the bricks were 5% cement, 40 -50% sand and 50 - 55% earth. Although, the technique for brick production was taken from proven methods of UNHABITAT and GTZ, various experiments were performed at the beginning to get the most durable and strong bricks.

Figure 2: *Brick Machine is used to produce CEB which are 1.5 times bigger than regular bricks.*

TREATED BAMBOO:

The bamboo used in the project was cured thoroughly. The bamboo was submerged in water and a small amount of borax for 21 days and dried in shade for another 7 days. The curing process resists the bamboo from termite infection. Moreover, once the project was finished, a coat of varnish was applied for longevity.

The bricks were placed without mortar, but every three feet, 3mm iron rods were placed to hold the bricks. Afterwards mortar slurry was inserted into the aligned holes. The fusion of mortar slurry and iron rods created strong internal columns to bind the whole structure.

Figure 4 *Construction process of the rural architecture of Bangladesh using new construction method.*

JUTE COMPOSITE TIN (JCT):

Using jute, resin and crystalizing agents, Jute composite tins were developed for the roofing material. Jute composite could be molded into any form of tiles. However, since rural masons are trained at making roofs with CI sheets, the same forms were replicated. Countless experiments were done with various proportions of resin and crystalizing agents. Moreover, various kinds of jutes with different thread counts and density were experimented to find out which one produced the strongest JCT. Finally, a superior quality JCT was achieved that is more strong and durable than regular CI sheet.

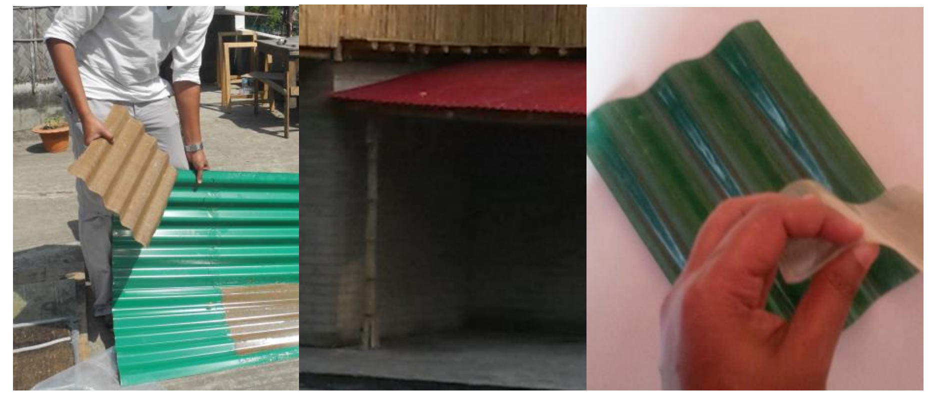

Figure 3*: Jute Composite Tin (JCT) made from jute, resin and crystalizing agents.*

SOCIAL APPROACH TO NEW CONSTRUCTION METHODS:

It is of course always a challenge to introduce a new method in the market, regardless of how good it is. Strong mindset about existing construction methods are hard to alter and new materials often fail to gain trust. Moreover, people do not want to take risks with their savings in new and unproven things. However, cost is a big factor in the rural areas of Bangladesh. People are attracted to cheaper yet better material. Once we finished constructing a 10’ x 20’ house with CEB in less than two weeks and in much cheaper price, high interest was generated among the villagers. The newly designed house built with earth, bamboo and jute looked more attractive and was much comfortable than a ci sheet house. In economy of scale, once the CEB and JCT will be mass produced, the cost of the house will also come down significantly.

	CI Sheet House	**Brick House**	**Earth – Jute House**
COMPARATIVE STUDY OF CONSTRUCTION METHODS IN RURAL AREA ON A 10’ X 20’ MODEL.			
Cost (100taka = 1Euro)	200,000 – 300,000 taka	500,000 – 1,000,000 taka	150,000 – 200,000 taka
Materials	CI Sheet, Iron, Wood, Cement	Kiln fried brick, cement, iron rods, concrete, wood, etc.	Earth blocks, cement, Jute Composite Tin, bamboo
Insulation	Very minimal insulation	High insulation	High insulation
Construction time	4 to 6 weeks	6 to 12 weeks	2 to 4 weeks
Comfort level	Low	Low to medium	Medium to high.

RESEARCH FINDINGS

Jute Composite Tin (JCT) was superior to Corrugated Iron (CI) Sheet in almost all the test. JCT is more durable than CI and GP sheets. Because of the properties of jute and resin, much higher heat insulation was achieved. The JCT is rust proof and contains no toxic materials like lead or sulfur. Since there is no iron involved it is completely saline water resistant. Sound proofing is higher and it has very low thermal expansion

	Corrugated Iron Sheet (CI SHEET)	Jute Composite Tin (JCT)
Cost (100 taka = 1 EURO)	5000 – 20000 taka per baan	10,000 taka per baan (*1 baan = 180 sq. feet)
Saline resistance	Subject to corrosion	Corrosion proof
Toxic material	Lead, Sulfur, Galvanizing material, corrosive iron etc.	Resin.
Heat required to produce 1 baan	600 – 700 degrees F.	No heat required.
Insulation and comfort level	Very low.	High

Compressed Earth Blocks (CEB) has been around for a long time and many researches have been done to show its superior quality over regular kiln fired bricks. In this particular project, we concentrated on environmental impact, insulation and usability.

The table shows the comfort index of users inside the building compared to the existing brick cement houses. Y axis represents air temperature while X axis represents hours during the day.

	Regular Kiln fired Bricks	Compressed Earth Blocks
Cost (100 taka = 1 EURO)	7 – 10 taka per piece	5-7 taka per piece (based on 1000 bricks per day)
Water resistant:	Yes	Yes
Environmental impact:	8 million tons of carbon emission in Bangladesh every year	Very minimal. CEB's are made with 5% cement stabilization, therefore carbon emission of cement should be considered
Heat required to produce 1000 bricks	1000 – 1500 degrees F	No heat required.
Mortar requirement :	Mortar cement is required for laying bricks and wall plastering	Mortar is only required to make internal columns
RCC Columns requirement:	Columns required every 10 – 15 feet for brick filling	No columns required. Walls are load bearing and internal columns are inserted through the bricks.

Cured bamboo was used instead of regular bamboo to extend the longevity of the building. If the cured bamboo is not found locally, it can be cured with minimal effort. The cost of curing needs to be added with the individual bamboo cost. The selected findings are given below.

	Regular bamboo	Cured bamboo
Cost (100 taka = 1 EURO)	100-150 taka per piece	170-200 taka per piece
Termite resistance	No termite resistance.	Termite resistance.
Availability	Widely available	Not widely available.
Processing time	Can be used directly after cutting	Need to cure for at least 3-4 weeks
Longevity	3- 10 years depending on annual perspiration.	20 – 50 years depending on maintenance

INFERENCES AND CONCLUSION

This particular type of material and construction techniques has a huge potential in rural Bangladesh. Furthermore, carbon emission is significantly reduced in the new method, resulting in a very positive environmental impact. Since the labor cost is cheap in Bangladesh, Compressed Earth Blocks (CEB) can be produced in large scale and in much more cost effective ways. As a result, the price of house will be significantly lower and more for the rural people. The CEB machine requires investment at the beginning. However, this also has potential to create local entrepreneurs. Moreover once the new methods enter mainstream construction, more masons and entrepreneurs will be interested to build with these bricks. Jute Composite Tin on the other hand will have rather big challenge to penetrate the market because of its high price. However, since it is rust proof and once the economies of scale will be achieved in mass production, it will have a significant advantage in the coastal areas where corrosion of regular CI sheet is a major problem.

ACKNOWLEDGMENTS

Eza Chowdhury, the client extraordinaire, who took a leap of faith and allowed her clinic to be made with experimental sustainable materials. 'Gold of Bengal' and Walid Ahmed assisted with jute materials and research data. Apu Roy with his team of bamboo workers from Dinajpur and Azoffor with his team of local masons from Faridpur worked tirelessly on the ground. The workers featured in the first page picture, not only built the clinic in shortest possible time, but also made significant contribution to data collection and research findings. Junior Architect Abir, Anwar and Sifat assisted in documentation. Lastly my wife Aurelie Rob, whose understanding, support and encouragement was vital for me to complete this research.

Proposal of a Methodology for the Architectural Design of Timber Houses

Luis Morgado, MArch Manuel Correia Guedes, PhD João Ferreira, PhD Helena Cruz, PhD

[Instituto Superior Técnico, Universidade de Lisboa] [LNEC, Lisboa]

ABSTR ACT

This paper presents the principles of a method for the architectural design of timber houses based on the experience gained by timber companies. This proposal has as its major goal the challenging of the scenario of countries like Portugal where a shift in the design and construction methods integrating wood as a material could result in a much more sustainable habitat. A set of interviews was carried out with Portuguese companies in the sector of timber houses. They were questioned about their customers, design methods, the architect's role and the choice of structural systems. Based on the interviews it was possible to characterize the market and identify the main procedures about design. The most relevant ones were the importance of the architectural type definition, the support of a catalog, the relationship between formal and structural types and the architect's lack of knowledge about timber. The collected information pointed to an architectural design method to be used by Portuguese architects who, until now have often played a secondary role when a timber house was designed partly because the timber companies dominate the whole process. Some of these companies offer catalogues of design solutions that support customer's choices. The architects generally reject this type of method because of its supposed uncreative and impersonal results. The method here presented through some basic principles aims at collecting some positive lessons from the catalogue method, defining a process based on the recognition of Formal types and Construction types. This is the framework of a tool intended to help the Portuguese architects to deal with the range of the options available (solutions, companies, structural systems) and a support to help in deciding which construction system to choose.

INTRODUCTION

The adoption by architects of an architectural design method based on the information provided by the experience of timber house companies could lead to an increase in the use of timber houses. The replacement of Portuguese current concrete houses would originate several environmental benefits. The sustainable use of wood in single-family houses has been the subject of studies which conclude that there are advantages in its use over conventional solutions such as reinforced concrete (Monahan & Powell, 2011; Monteiro & Freire, 2012) and even over competing systems, such as light steel framing (Bolin & Smith, 2011; Rabbit, White, & Gervais, 2012). It is argued that the replacement of wood construction materials could result in a reduction of carbon emissions (Sathre & O'Connor, 2010). Even recognizing that there is no consensus on the results of such studies (Coelho, 2012; Gervasio, 2013) there are other arguments to consider when dealing with timber construction: the construction time and the prefabrication level. The average construction time for the current single-family houses in 2012 was 25 months (INE, 2013) while the construction time for wooden houses in Portugal is less than 6 months (Morgado & Pedro, 2011).

Although Portugal has a forest richness that could, with a growth in domestic demand, provide some of the raw material for construction (Marques Morgado, 2012; Machado, 2004), the old tradition of building some house elements such as roofs, floors and some walls with wood was lost. But in the final of the 20th century the scenario began to change with the appearance of pioneer timber house construction companies. Usually the whole design process was managed by these companies almost without the advice of architects. Besides, until recently structural wood was not considered by Portuguese architects as a solution. Today their growing interest by timber houses can be observed through three situations: 1) the presence of timber construction companies that integrate architects or are managed by them; 2) the emergence of a small number of architects who become specialized in timber construction; and 3) the proliferation of commercial or academic proposals for modular house designs in timber, with high impact on the architectural community, but with reduced reception from the real housing market. Moreover, the single-family house is one of the most important works of Portuguese architects (Domp, 2014). This way the architects, required by law to design a house (Law n. º 31/2009), are very well positioned to inform their clients about the possibility of building with wood. Additionally, houses in Portugal are one of the most significant types of the building housing stock: 13.500 houses were built in 2012 against 1.212 apartment buildings (INE, 2013). However the architects' current design method may not be appropriate to timber house design. So this work does not focus on specific house solutions to reduce energy or to improve carbon sequestration. Instead of this it proposes a general method to allow architects to put into practice a more sustainable type of construction using wood, replacing the common practice of choosing by default concrete and brick.

Objectives and methodology

The objectives of this article are:

1) To provide a summary of the results of 15 interviews with Portuguese timber house companies;
2) To propose the principles of a design method based on some aspects of companies' experience;
3) To identify the relevant typological principles connected with timber construction in Portugal;
4) To identify the main issues to integrate in design procedures;
5) To identify the relevant criteria for choosing a timber structure from the set of various solutions.

The current work involved:

1) The review of related literature and continuity with the research already carried out by the authors (Morgado, Guedes, Ferreira, Cruz, 2013; Morgado, Guedes, Ferreira, Cruz, 2012);
2) Interviews with managers, technicians or sales technicians;
3) Analysis of the interviews;
4) The proposal of a method to support architectural design through its basic principles.

Initially 25 companies were pre-selected and contacted, because they were among better well-known companies in the Portuguese market or represented the diversity of the national reality. Because of this, companies that do not refer the product "House" in their advertisements, or those whose structure seemed to be very fragile or only with a very short period of activity have not been considered. From the group of selected companies, 15 were interviewed with predefined questions and 10 showed no availability to answer. The interviews took place between April 10 and May 8, 2014, having been made in most cases in the headquarters of each company. Only in one case the interview was conducted using a form filled online.

The interviewed persons were: ten managers, two design technicians and three sales technicians. The headquarters of these companies are located in a vast territory extending 380 kilometres of the Portuguese coastline (up to about 60 km east inland) from Vila Nova de Cerveira (north) to Setubal (south). Timber houses account for over 80% of the workload of seven of the interviewed companies, while in the other eight there is a variation between 5% and 55% of their area of activity.

The interviews were supported by a questionnaire with eight main groups of questions: 1) Companies information; 2) Clients; 3) Construction Process; 4) Conception and design; 5) Role of the architect; 6) Choice of structural systems; 7) Structural systems' features; 8) Design method. The interview will be analysed as a whole in another publication, so only the relevant questions for the goals of this paper will be considered.

THE INTERVIEWS

In the context of design methodology, national companies were classified based on the following criteria: the level of integration of the architect's activity, the number of building systems offered and the main companies' activity. Thus seven companies regularly work with architects, four occasionally work with them and the other four cover a market in which the activity of the architect is residual. Regarding the number of structural systems available for clients to choose from, seven companies offer three or more systems, four companies have only two systems and the other four companies emerge with just one structural system. All companies include design and construction activities (inside the company or with external partners) and five of them do not manufacture their products, as they are just partners of foreign factories.

Construction systems

The dominant building systems are light timber-frame panels and post-and-beam, offered by eight companies and also the log construction present in six companies. With only three answers each system, appear cross laminated timber (CLT), light timber frame, plank and columns, three-dimensional modules and heavy mixed systems are present in three companies. Four companies offer heavy mixed systems (post-and-beam with light timber frame, planks or logs). The preferred system of most companies is the light timber-frame panels with four choices, followed by post-and-beam with three choices and cross laminated timber, light timber frame and heavy mixed systems with two choices.

Clients

From the point of view of the interviewed companies, the arguments that lead a customer to choose a timber house are the Comfort (ten answers "very important" and four "important"), followed by the special architectural Aesthetics associated with wood (seven "very important" and six "important") and the Speed of construction process (five "very important" and ten "important"). The Environmental factors (three "very important" and five "important") and economics (three "very important" four "important") are less consensual. Regarding the type of agents who contact those companies, the final consumers are the most frequent, followed by architects. Most companies say that customers who approach them had already decided to build in wood. However the contacts are usually made in order to get a quote to compare with quotes those clients already have from other companies.

Construction process

The most common construction process consists in the prefabrication of components regarding the specific settings of each project (twelve answers "often" and one "occasionally") and it is also common to use prefabricated market standard elements (five answers "often" and nine "occasionally"). However, the onsite manufacture with reduced prefabrication is still considered cost-effective by some companies (four answers "often" and three "occasionally"). Some companies work with complete modules (three answers "often" and three "occasionally") or partial modules. All companies considered that distance is not a limiting factor of the project's viability, although it may increase the final work cost. The final prices quoted by companies for a wooden house ranges from about € 500/m2 up to € 1000/m2. The average price indicated by the 15 companies is about € 800/m2.

Method and design conception

Most companies (with one exception) consider, among other possibilities, the timber house design as a completely custom solution. All companies include a showcase of solutions available for client consultation, functioning in some cases as "catalogues of solutions" or books of patterns. This is a common device in the companies activity, whether based on pre-defined solutions (eleven responses), or based on a customisable modular system (six responses). The companies with a larger production of houses tend to offer a detailed catalogue presenting different types of solutions grouped in families of "styles" and structural types. Only two companies declared not to provide such a device, coinciding with situations where timber houses are a secondary activity. Among companies using the catalogue of solutions, only two considered it to be "less important", with the others considering that it is "very important" (five responses) or "important" (six responses).

The purpose of the "catalogue of solutions" is for most companies (seven responses) a reference to support customer choices, with only two companies considering that the catalogue offer products that customers actually accept and buy without any changes. Four companies considered that catalogues work more as a marketing medium. It was noticeable that several companies use their already built houses or their exhibition prototypes as models that act also as a "catalogue". When addressing the companies, most customers already have a pre-set idea of the functional type of house they want to build (twelve responses), but are often less informed about the symbolic type (language, proportions, details, finishes) and it is frequent that they are not enough aware about structural type definitions. Although with less answers, the client without predefined ideas also consults the companies for the support of the design services from early stages (two answers "often", nine "occasionally"). Architects, as expected, consult those companies with more defined ideas about functional and symbolic solutions, although not often with pre-defined ideas of the structural types. Companies use the pre-defined customer ideas as a starting point, although some minor adjustments (fourteen responses) are always required. When customers do not have pre-set ideas the most widely used process is the customization of solutions based on the catalogue (eight responses) and the definition of completely customized solutions process.

The architect's role

All companies offer architectural design, structural engineering and the other engineering services. However seven of them hire external architecture services and other seven hire external structural engineering services. The intervention of architects, in addition to the design development phase for authorities' approval, is generally lower in the phase of construction documents and in the coordination tasks. It should be noted that normally, in cases where the architectural services are hired by the client, the company prepares a set of documents to be reviewed by the architect responsible for the design approval. Regarding the knowledge of timber construction specificities, the architect is seen by companies as a professional who demonstrates "many difficulties" (seven responses) or "some difficulties" (seven responses). The most highlighted aspects were the difficulties about durability constraints (eight responses "many difficulties" and five "some difficulties"). The structural and hygrometric behaviour of wood and the construction details were also highlighted, although not with so much importance. It may be added that one of the interviewees considered that cases where the architect's solutions fail are explained by the importing of architectural models from central and northern Europe, whose performance in the national climate (thermal and humidity conditions), turn out to be deficient. The architect is nevertheless considered an important partner, as expected, for the completion of approval designs, the implementation of the program and the definition of formal solutions. Questioned about whether the intervention of the architect leads to more complex, more expensive, or later problems, most companies found that that it does not affect the normality of the work, although some companies indicated negative responses and no company indicated that the architect's intervention has a positive effect on these parameters. Five companies answered that architects are responsible for more complex processes, four mentioned higher costs and three mentioned later problems. Most companies defend that the structural engineering must be integrated in the company (eight responses), opposite to a minority (four responses) that consider that it should be integrated into the project team or that should be hired by the company (two answers). Some companies noted that when the structural designs are undertaken by external offices, the structural components tend to be the oversized.

Choosing the structural systems

During the initial project definition, clients do not usually think about structural systems. Half the companies responded that it is rarely mentioned, while three considered that this aspect is never mentioned. The choice of structural types occurs frequently (seven responses) and occasionally (eight responses) simultaneously to the choice of the formal type. It is also frequent (nine responses) and occasional (three responses) that the choice is made after the formal type definition. Only in three cases was the choice of structural type done beforehand (frequently and occasionally). The simultaneous choice of structural and formal types occurs mainly in cases in which companies have an organized catalogue of solutions associating a structural type to each formal type. Some interviewees mentioned that when clients choose as a reference the catalogue solution, they already know which structural system will fit better.

The choice of the structural type which is usually held in the early stages of the project is done by considering the adequacy to the architectural solution as the most important criterion (nine responses "very important" and three "important"). The remaining criteria are less important, but economy is still the second most mentioned criterion, being considered as "very important" (four responses) or "important" (three). The other mentioned criteria are the construction schedule, the quality of the construction process and finally, the environment is considered a "less important" criterion (ten responses) or "not important" (four responses). Regarding codes and standards, the majority of responses devaluates its impact on the choice of the structural system, with most companies responding that their influence is less important or unimportant. However, the thermal requirements are those to which companies assign more importance over the other ones (structure, aesthetics, specific timber standards), with one "very important" response and four "important" responses. For the characteristics of the built envelope, seven companies said that different climatic zones have influence in their settings while eight said exactly the opposite. These latter companies said that the offered solutions always include the definitions to face in the most unfavourable situation.

The influence of structural types on the settings of formal types was considered mainly as "less important" (nine responses) or "unimportant" (two answers). The comparative analysis of structural systems is undertaken "often" or "occasionally" by seven companies, and "rarely" or "never" by the remaining eight. When questions were asked about the adequacy of structural systems to specific architectural characteristics, the responses were predictable, associating the post-and-beam to wide structural spans and larger windows, interior open spaces, stylistic flexibility, contemporary and "structural truth" character. The light timber frame panels were associated to stylistic flexibility, contemporary character and with minimized loads on the foundations. The log construction and the column-and-planks were associated to the "structural truth" character and the traditional character (though one company does believe that the contemporary character is also possible). The cross laminated timber panels are also mentioned, but less often (because only three companies work with them), associated to large spans, protruding volumes, stylistic flexibility and contemporary character.

Design process

Most companies (fourteen responses) can easily provide a construction cost estimate with a sketch drawing (1/200 scale), implying the existence of reference prices per square meter, although there are additional factors to consider such as the level of quality of finishes and the scale factor, reducing the price by square meter as the amount of work increases. With a design development project (1/100 scale), all companies already provide a final budget. Companies are flexible about the time the contract administration should take place, most of them (nine responses) considering that this step must only occur after the municipal approval is obtained. Throughout the interviews development, it was noted that the issue of construction documents (construction drawings) phase executed by the architect only occurs in some cases, as a large part of the details and specifications are made by the company. The detail drawings of architecture tend to be complementary (when they do exist) to manufacture and assembly drawings of the structure, envelope and interior partitioning. Seven companies think that the construction drawings must be coordinated by the company, while four answered that it should be a simultaneous process.

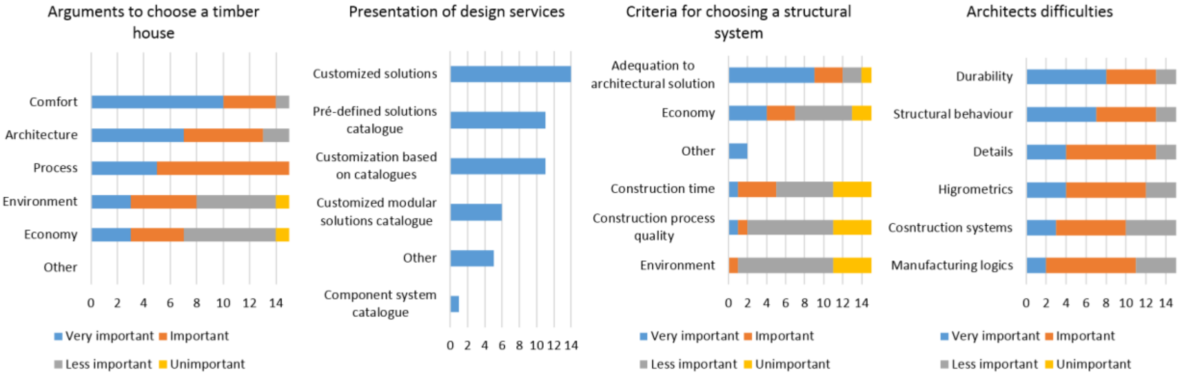

Figure 1 Some interview results based on 15 answers: (a) Arguments to choose a timber house (b) Presentation of design services (c) Criteria to choose a structural system (d) Architects difficulties.

ARCHITECTURAL DESIGN METHOD

An overview of the design process adopted by companies of timber houses and architects in Portugal can be described through the following three reference models (A, B, C):

A **-** Developed by the timber house sector companies. With solutions built from tested designs or catalogues or still modular systems (although contemplating customization). The companies have a preferred range of structural systems to offer. The architectural services in each project can be minimized due to the accumulated experience and the repetition of solutions. The advantages of this process are construction quality and process efficiency. Architecture in this case is understood as a product. The client chooses the product, but he must adapt himself to the company's standards and offer.

B **-** Developed by architects according to the model propagated by architecture schools in Portugal. With solutions based on the specific nature of each commission and ruled by conceptual principles or inspiring models of contemporary architecture, with the aim of obtaining unique and innovative features, with a large investment in aesthetics, more than durability. The architect integrates the well-known construction system with reinforced concrete. The architectural services are carried out with great endeavour in construction drawings. The advantages of this process are its formal quality and uniqueness. The resulting architecture is seen as an artistic product. The client chooses the architect, but he should adapt himself to the architect’s choices.

C **-** Developed by architects who provide services adapted to the reality of the average client of the single family houses in Portugal, with the aim of their satisfaction. With solutions based on preferred customer models and with reduced conceptual and aesthetic thought. The building system makes use of the current reinforced concrete. The architectural services are performed with reduced effort in construction drawings, using known details. The advantages of this process are the smaller costs of the design services, and the improved customer satisfaction, but the resulting architecture is often a rather banal product. The customer chooses the architect and this one must then satisfy his particular requirements.

We want to propose now an alternative system: D **-** To be developed by architects under a collaborative process with wooden houses sector companies. With solutions developed from a knowledge base made by a "catalogue" of architectural types which provides information on achievable solutions with timber structures, recognizing customer preferences but expanding the range of available solutions and the suitability to each scenario, with great emphasis in construction drawings, in durability concerns. The advantages of this method, compared to the process A, are the greater range of customer choices and the independent support that is provided. Regarding process B, communication and customer satisfaction are improved by a choice supported by a typological catalogue, seeking to obtain durable solutions. Finally, in relation to procedure C, there is the advantage of offering a personalized service with greater effort in architectural thought and greater conceptual attention to context and a more sustainable solution in wood.

Typological systematization

The typological systematization of the timber houses universe will be part of the information that allows us to acquire knowledge of market possibilities and that enable the communication between architect and client. The set of possible types results from the subdivision of architectural types into subtype systems. Thus, each architectural type includes a formal type and a construction type. The first is defined by features of architectural design, while the second is defined mainly by engineering features. The architectural type can in turn be subdivided into functional, spatial and symbolic types (Figure 3). The construction type can be subdivided into structural, envelope and partition types. Although the “types” can be described by rules, thus being different from "models" (or concrete solutions), it is useful to build a "catalogue" with models which represent the main types, because it will improve the communication between the client and the architect, avoiding misunderstandings. Dialogue can be established enabling the client to make choices from the various possibilities. On the other hand, architects can advise the client about the most adequate type of solutions without missing possibilities. The symbolic type is particularly important in the context of architectural types. It is defined in terms of characteristics, such as the roof shape, the degree of openness and the kind of finishing. The structural type (Morgado, Guedes, Ferreira, & Cruz, 2012) is of great importance in the context of building types, defined according to the characteristics of its vertical elements.

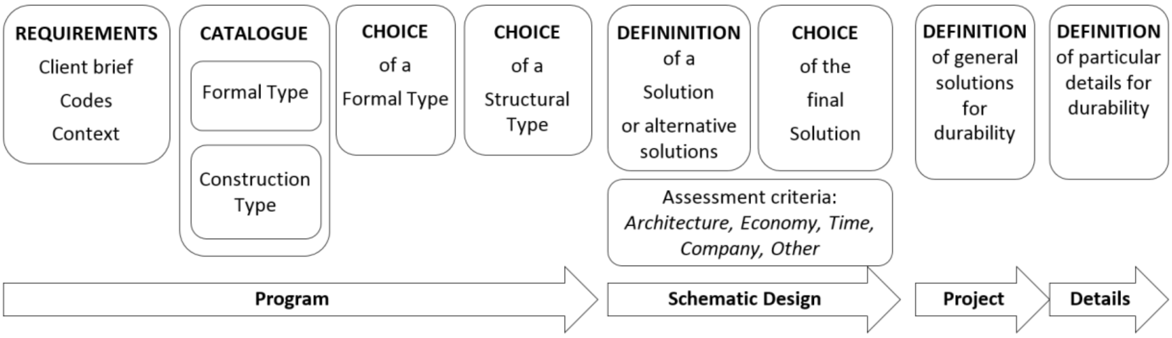

Figure 2 Proposed procedure based on architectural types.

Proposed design method

After the collection of data gathered from the context (codes, standards and customer requirements which include the functional requests, values and preferences, cost limits, time limits and environmental sensibility) the program is defined by the architect. The program will be based on the definition of successive types: functional type, spatial type and symbolic type which together define the formal type. After that the construction type will be defined: structural type, envelope type and partition type, but at any time the decisions can be questioned, thus implying a comeback to any previous stage. In the sketch design phase, solutions are developed and evaluated based on the selection criteria and respective weights defined in the previous phase. The structural solution (or structural solutions, in case there exist alternatives) will be evaluated based on the suitability to the architectural solution, the economy (including the costs provided by companies), the process (including deadlines and assessment of companies) and possibly on environmental impacts of the solution and also other criteria defined for each case. After the solution and the construction company have been chosen, the activity of the architect, besides the integration of all engineering services, will be focused on the architectural features that can ensure the durability of the building through the general settings and particular details.

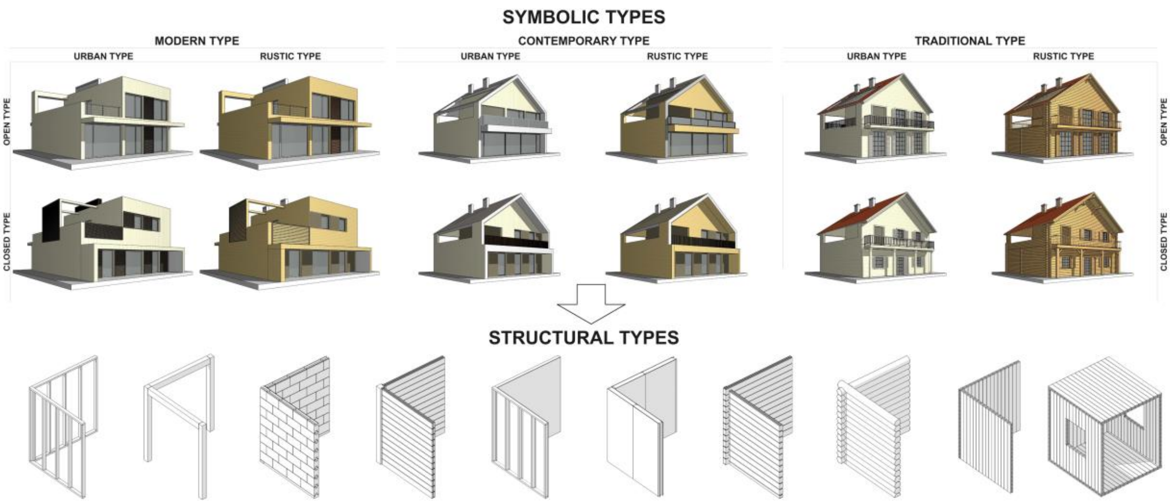

Figure 3 Example of a typological catalogue made by symbolic types and structural types

Following this proposal it is required that the architect welcomes a set of new practices and new skills: 1) It is required a knowledge of the cultural aspects of wood architecture to support the choice of formal types; 2) It is required a knowledge of structural systems and the understanding of its relation with architectural forms; 3) It is required an awareness of the criteria for selecting the structural types; 4) This calls for a better understanding of the specificities of wood and the constraints of durability. Architectural firms interested in building wooden houses could also define their own catalogues, following the suggestion of Colin Davies (Davies, 2005): "Pattern books could be used to promote the sale of certain commercial products, but more importantly, they could also be used to promote good architecture and sound, sustainable building practices (…) It seems completely feasible for architects to adopt, or readopt, the pattern book principle. It may even be an essential precondition for the achievement of that century old ambition to bring architecture to the masses".

CONCLUSION AND DEVEOLPMENT

Based on interviews conducted with the timber houses design, manufacture and construction companies, it was possible to recognize some important aspects of the national market and of the design process. Based on the information collected, the framework for a proposed method targeting the optimization of timber house design in Portugal was outlined. The information that had greatest impact on the proposal were: the existence and the importance of a typological catalogue, the relevant criteria for the choice of structural type (suitability for the architectural solution, cost limits and time limits), and the difficulties evidenced by architects in relation to wood construction. This last situation requires some actions to improve the knowledge about wood considering the solutions' durability. The details of this proposal are in development within a Doctoral Thesis, with several Portuguese companies supporting case studies aimed at testing the characteristics and constraints of each construction system.

ACKNOWLEDGMENTS

This paper was only possible due to the friendly collaboration of the following Portuguese enterprises: Casema, Carmo, Colicapela, Fuldex, Ideawood, Jular, Lacecal, Logdomus, Loghomes, Novo Habitat, Pinho Casa, Portilame, Rusticasa, Toscca and Tisem. We particularly want to thank the persons (managers, technicians and commercial technicians) from each company, who dedicated part of their time to participate in the interviews: Nuno Rebocho, Susana Valente, Tiago Antunes, Carlos Silva, Amilcar Rodrigues, Helder Santos, João Carmo Simões, Sérgio Barbosa, Pedro Teles, Elisabete Ferreira, Veascelav, Luís Rocha, Berta Villas, Pedro Pinhão and Luís Jorge. We also wish to thank the FCT - Fundação para a Ciência e Tecnologia do Ministério da Ciência, Tecnologia, e Ensino Superior.

Window Components' Heat Control versus Orientation under the Extreme Hot Climate of the UAE

Kheira Anissa Tabet Aoul
United Arab Emirates University

Tareq Abuimara
United Arab Emirates University

ABSTRACT

The United Arab Emirates (UAE) has one of the world's largest energy consumption per capita, with the building sector accounting for 70% of the consumed energy, used primarily for cooling due to its extreme hot climate. Recently, the government launched several housing programs intended to meet the need of future Emirati beneficiaries, of which the Emirati Family Housing Program aims at providing 13,000 detached residential units by 2017. Orientation of typical housing design is solely governed by urban planning layout. More critically, windows did not show any adapted heat control treatment in relation to orientation, despite the windows significant impact on heat gains under the local extreme hot climate. This study aims at optimizing the thermal performance of the window's components in relation to orientation in a typical house. The impact of orientation in the exsiting design indicated a 10% higher energy consumption for the west-oriented units compared to the east ones. Thereafter, the impact of window's components including glass (double reflective glass, double tinted Low-E and double squared Low-E), frame (vinyl) and a shading device (automated slated blinds) were tested. The best performing components were then combined into two scenarios: the first one included a vinyl frame and double tinted squared Low-E glass and the second had Low-E glass, vinyl frame and automated slatted blinds. The results indicated a reduction of the total annual energy consumption ranging between around 6% when facing east and 13% when facing west. More importantly, the optimal window components highlighted similar performance independently from orientation.

INTRODUCTION

The reduction of buildings' environmental impacts is an internationally agreed agenda. A number of studies have established that urbanization is one of the main drivers behind environmental impacts including global warming, depletion of natural resources and air pollution (Smith, 2005, Seto et al, 2011). The building sector in the United Arab Emirates (UAE) has experienced a tremendous expansion in the last forty years due to population growth and economic development. Presently, the UAE has one of the world's largest energy consumption per capita, with the building sector accounting for 70% of the consumed energy. The residential sector in the UAE accounts for about 65% of newly constructed buildings according to the National Statistics Center (Statistics Center, 2013) and is responsible for 39% of the consumed energy, used mainly for cooling purposes (Saifur, 2012; RSB, 2013) (Figure 1). Amidst the overall country's growth, the residential sector developed in the form of extensive housing programs provided by the government to its citizens. The majority of these housing programs are in the form of detached houses, the most demanding type of houses in terms of cooling, especially under the local extreme hot climate (St Clair, 2009). A survey of housing typology in a representative community highlighted typical housing design where the units' orientation is solely governed by urban planning layout (Abuimara, 2013). More critically, windows did not show any adapted heat control treatment in relation to orientation, despite the windows significant impact on heat gains under the extreme hot climate. This paper presents the result of an experimental investigation that explored the potential contribution of advanced window's components to optimize the thermal performance independently from the impact of orientation while maintaining the architectural design unity.

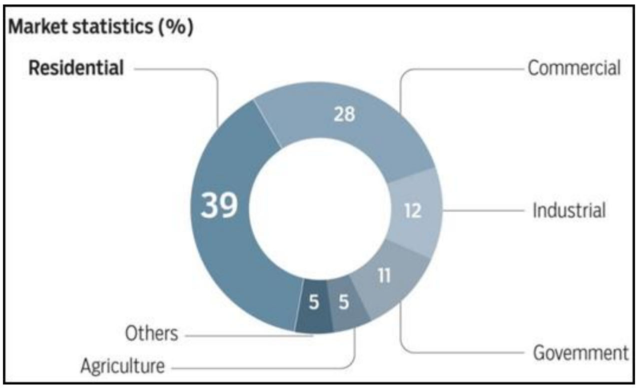

Figure 1: Energy Consumption by sector in the UAE (Source: Saifur, 2012)

HOUSING DESIGN, ENEGRY EFFICIENCY AND CLIMATIC CHALLENGE IN THE UAE

The UAE's desert climate, characterized by extremely high summer temperatures, imposes serious challenges to both designers and owners alike. Despite the extreme hot climate, controlled building thermal regulations were not introduced until 2003 in Dubai, addressing envelope insulation and glazing requirements in an attempt to curb the increasing energy issue in the building sector. These prescriptive insulation guidelines were then incorporated since 2011 in the Green Building Regulations (DEWA, 2014). More recently, the Urban Planning Council (UPC) in Abu Dhabi has established *Estidama*, the local green building rating system, This, aims at achieving sustainability and energy conservation in buildings through the provision of guidelines for newly constructed buildings. However, these guidelines are not fully implemented as they are still in the process of integration to the local building code (AlNaqbi et al, 2012).

Since the discovery of oil in the sixties, the UAE government amplified its intervention in the housing sector, acting as the main housing provider for its citizens at both federal and local levels. Governmental housing has evolved over time and comes currently in the form of communities that comprise a large number of detached houses (Abuimara, 2013). The *Emirati Housing Program* is the most recent program launched by Abu Dhabi Urban Planning Council (UPC), aiming to provide 13,000 detached houses until 2017 in the form of communities and neighborhoods in cities of the Abu Dhabi Emirate (UPC, 2011). These communities aim at the accommodation of social and cultural values along environmental adaptation through the design and construction of modern, high quality, sustainable units meeting *Estidama* requirements (Estidama, 2014). Al Falah Community; the research case study, located near the city of Abu Dhabi is part of the *Emirati Housing Program* and includes a substantially completed number of detached houses (ALDAR, 2009).

THE CASE STUDY; AL FALAH COMMUNITY IN ABU DHABI

Al Falah master planned community, part of Abu Dhabi 2030, has been designed to provide community facilities along with alternative social housing options for Emirati citizens. It consists of five residential villages with a total of 4,857 detached villas including a range of community amenities (Figure 2). Houses at Al Falah come in nine different designs varying in terms of size and architectural style. Villas come in three, four and five bedrooms typology ranging respectively from 300m^2, to 350 and slightly over 400m^2. All houses are located in large plots of over 1000 m^2 (30m x 35m), and surrounded by 2.5m high boundary walls (ALDAR, 2009). The villas were designed in 2008, prior to the development of Estidama; the local green rating system. They include some general sustainability measures including external wall and roof insulation, efficient water fixtures and high performing ventilation and air conditioning units (G.M.H. 2009).

Figure 2: Al Falah master plan community and aerial view of phase 1 (RIAS, 2013)

The three different architectural styles, labelled *Andalusian*, *Heritage* and *Modern* as illustrated in Figure 3, share otherwise the same layout (ALDAR, 2009). The master plan layout governs houses orientation with no indication of any window treatment adaptation per orientation.

Figure 3: The three different architectural styles (Andalusian, Heritage and Modern) of the same five bedroom layout houses in Al Falah community (ALDAR, 2009)

EXPERMENTAL INVESTIGATION

First, the dominant type of houses was identified through a typological classification survey of all houses. The five-bedroom villa emerged as the dominant type accounting for 50% of the total number of houses in Al Falah community, while 20% were 3 bedroom houses and the remaining 30% were four-bedroom houses (Abuimara, 2013). Next, a comparative evaluation of the Window to Wall Ratio (WWR) in all living spaces was reviewed and compared among the three architectural styles. Ranges of WWR of 24% to 30% and 50% to 60% were identified respectively for bedrooms and the living room indicating potential for window design optimization (Abuimara, 2013). The modern style house exhibited an overall slightly higher WWR than the other styles and was selected as the case study (Figure 4). Table 1 summarizes the characteristics of the base case including location and the building construction characteristics.

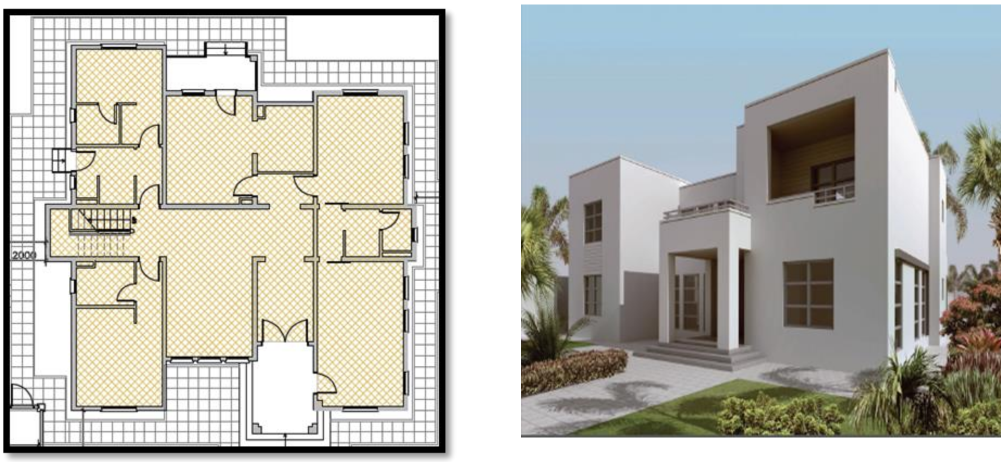

Figure 4: The dominant house type in Al Falah community; the five bedroom modern style house ground floor plan and main façade perspective

Table 1. The Base Case Characteristics

Category	Item	Description
Site	Location	Abu Dhabi 24.42^0 N, 54.65^0E
Area	Total Area (GF+FF)	402.36 m^2
	Footprint	212.56 m^2
Building Envelop Materials	Windows	Tinted double pane glass with air gap in aluminum frame (U-value= 0.81, SHGC = 0.45 and Tvis = 0.57)
	Walls	Insulated concrete panels. (20cm thick concrete panel with 6cm polystyrene insulation) R=11; Calculated using Opaque (Version 2) software based on the existing construction details
	Roof	Hollow core concrete slab with water proofing and heat insulation layers R=18; Calculated using Opaque (Version 2) software based on the existing construction detail.
	Wall / Ceiling reflectance = 70%	Colors range between white and cream (construction documents: ALDAR,2009)
Ratio of Glazing per Façade	Front Façade	26.55%
	Right Side Façade	13.4%
	Left Side Façade	9.03%
	Rear Façade	16.2%
Air Conditioning System	Package Unit	Seasonal Energy Efficiency Rate (SEER)=13
Indoor Temperature	Lowest indoor comfort degree = 21.1 C (70F)	According to California Residential Code
	Highest indoor comfort degree = 23.88C (75F)	

The impact of orientation on the thermal performance of the existing house design (base case) was first tested using the Home Energy Efficient Design software (HEED 4.0 build 34); software developed by the University of California Los Angles (UCLA). HEED is a dedicated energy evaluation tool for the thermal performance of houses and its outputs include among other data the annual electrical energy consumption, cooling loads and lighting loads.

The next step, in line with the original objective of this research explored thermally improved window components that do not impact the building architectural style. A reduction of window-to-wall ratio as well as addition of external shading devices as needed per each orientation were not considered. Hence, optimized glass alternatives and window frames were first individually assessed for each orientation in order to identify the contribution potential of single items. The glass and frames selection was based on their improved thermal properties and their availability in the market and included the tinted double pane Low-E glass, the tinted double pane Low-E squared glass and the tinted double pane reflective glass while the frame was limited to vinyl frame (Cardomy & Haglund, 2012). In terms of window shading, external operable slatted blinds were selected for implementation on all windows. These automated slatted blinds are light colored venetian blinds that close if the sun is on the window and interior temperature is above the set comfort level. The blinds are either fully open or fully closed. The selection of this type of automated blinds meets two requirements. First, they can be adjusted to suit all orientation in residential neighborhoods similar to the one under study, with thousands of houses allocated in different orientations that otherwise would have required specific shading designs for each orientation. Second, it maintains a distinctive uniformity as a specific orientation based design would have conflicted with the research objectives that aim at maintaining the architectural appearance of houses. Finally, a combination of optimum window components was carried out.

RESULTS AND DISCUSSION

Orientation Impact; Base Case

The impact of orientation on the annual thermal performance and the derived energy consumption was assessed. The annual electrical energy consumption, cooling loads and lighting loads for each cardinal orientation of the existing design are presented in Table 2.

Table 2. Base Case Annual Energy Consumption, Cooling and Lighting Load per Orientation

Power Usage (Kwh)	Orientation			
	North	South	East	West
Total Annual Electrical Energy	46,087	46,048	43,200	47,393
Cooling Load	29,455	29,434	27,163	30,400
Lighting Load	1,677	1,671	1,868	1,714

The first observation highlights a variable load for each orientation, emphasizing the impact of window design on the total energy used (Figure 5). The change of orientation with the main façade's higher ratio of glazing affected variably the annual energy consumption. The highest annual energy consumption rate was for the west orientation, while the east orientation displayed the least.

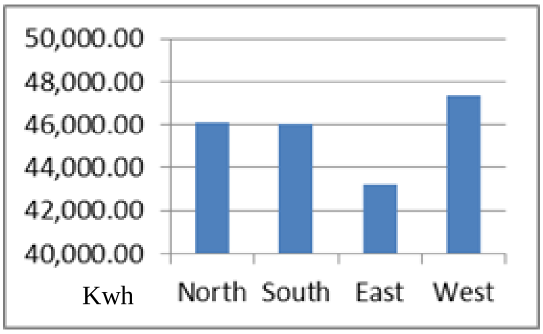

Figure 5: The Base Case Annual Energy Consumption per Orientation

The North and South orientation shared similar energy consumption rates.The recorded difference between the highest and the lowest annual energy consumption rates was 8.85%. This reduction in annual electrical energy consumption is linked to the reduction in cooling loads as it was reduced by 10.65% when the orientation changed from west to face east. This reduction can be explained as the east facing facade receives the least amount of solar radiation in the morning while the temperature is still low while the west facing receives the afternoon and evening direct solar radiation along with transmitted heat at day heat peak times. Finally, despite the use of window system with tinted double pane glass in the original design, the impact of orientation heat gains as verified remains, justifying the need to explore further the optimum potential of window components' heat control.

Thermal Performance Optimization

A vinyl frame with thermal break and three alternate types of glass were considered as indicated along their chgarcateristics in Table 3. The impact of these single component changes on the annual energy consumption per orientation is presented in Table 4 and Figure 6 for the glass alternatives contribution.

Table 3: Thermally Improved Glass Alternatives

Variable	U-Value	SHGC	Tvis
Tinted double pane glass, Aluminium frame with no thermal break (Existing Design) – Base Case	0.81	0.45	0.57
Tinted double pane glass, Vinyl frame (thermal break)	0.51	0.38	0.57
Tinted double pane Low-E glass, Aluminium frame	0.69	0.39	0.53
Tinted double pane Low-E squared glass, Aluminium frame	0.67	0.25	0.38
Tinted double pane reflective glass, Aluminium frame	0.81	0.16	0.09

Table 4. Total Annual Energy Consumption for Optimized Glass

Variable	Total Kwh			
	North	South	East	West
Base Case	46,087	46,048	43,200	47,393
Tinted double pane glass, Vinyl frame	43,624	43,571	41,464	44,664
Reduction	5.35%	5.38%	4%	5.76%
Tinted, double, Low E-Glass	44,626	44,580	42,225	45,709
Reduction	3.17%	3.19%	2.26%	3.55%
Tinted, double, Squared Low E-Glass	43,072	43,045	41,846	43,663
Reduction	6.54%	6.52%	3.13%	7.87%
Tinted, double, Reflective Glass	44,665	44,616	43,573	44,869
Reduction	3.10%	3.11%	-0.86%	5.33%

The results indicate that the highest savings in total annual energy consumption were obtained for all orientations with the double tinted squared Low E glass. The savings were from almost 8% in the case of west-facing house, 6.5% for the north and South and 3% in the case of east-facing one. The vinyl frame outperformed the aluminum one and contributed with a 4% reduction for the east façade and slightly about 5% for all the other orientations.

It should be noted that the total annual electrical consumption does not highlight the differential impact of each type of glass on lighting and cooling loads. On these grounds, the tinted doubled Low E glass generated 6% to 10% savings in cooling loads in comparison to the base case, indicating better heat control. The double reflective glass on the other hand, produced fewer saving because of the excessive lighting loads which ranged between 110% and 130%, due to the low visible transmittance of the reflective glass which led to an increased dependency on artificial lighting. In summary, if the double reflective glass indicates a better heat control, this is countered by its low light admission that will adversely affect lighting load, leaving a negative annual energy usage balance.

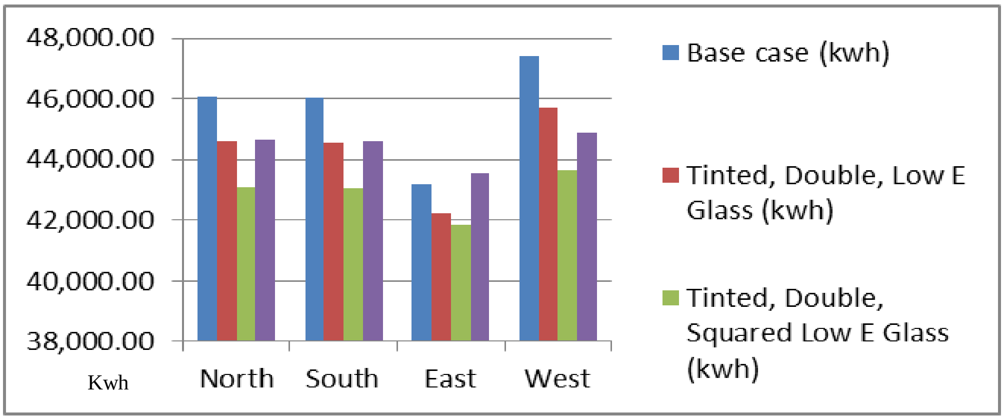

Figure 6: The Annual Energy Consumption per Orientation for Alternative Glass Options

Window Systems Thermal Performance Optimization

The next step consisted of optimised combinations of glass, frame and one type of shading devices. Two scenarios were considered; the first thermally optimized window system consisted of a vinyl frame with the double squared low-E glass and the second scenario had a vinyl frame, double low-E glass and shading in the form of light colored automated slatted blinds. The results indicate savings from 6% to almost 12% for the first scenario (Table 5 and Figure 7). Of more relevance, it should be stressed that the four orientations yielded similar annual energy consumption with marginal variation (1 to 3%) compared to the base case.

Table 5. Total Annual Energy Consumption for Optimized Window Systems (Scenarios 1&2)

	Total Kwh			
	North	South	East	West
Base Case	46,087	46,048	43,200	47,393
Scenario 1: Tinted, Double, Squared, Low E+ Vinyl Frame	41,407	41,429	40,551	41,839
Reduction	10.15%	10.03%	6.13%	11.72%
Scenario 2: Vinyl Frame +Low E Glass+ Slatted Blinds	41,136	41,046	40,439	41,107
Reduction	10.74%	10.86%	6.40%	13.26%

The second scenario with vinyl frame, Low E-Glass and automated slatted blinds carried a potential annual energy savings from 6.5% for the east and up to 12.7% for the critical west orientation (Table 5 and Figure 7).

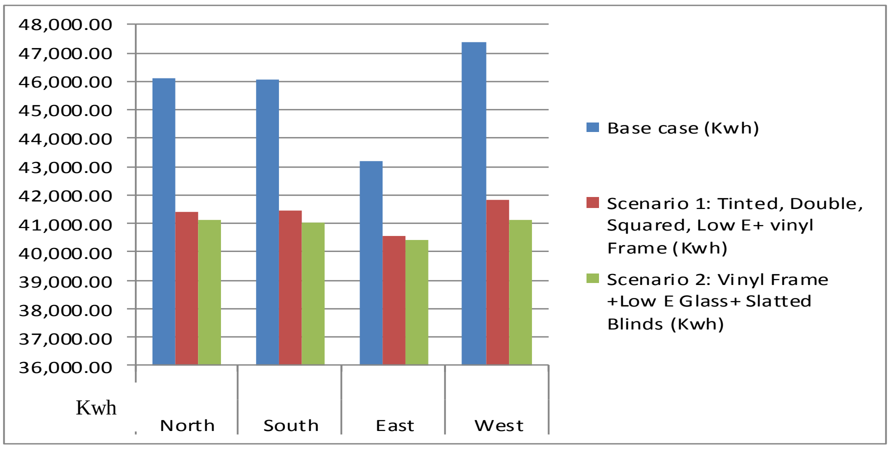

Figure 7: Total Annual Energy Consumption for Optimized Window Systems (Scenarios 1&2)

These savings are due to the reduction of direct solar gain which is being blocked by the automated shading device and the reduced transmitted heat the usage of low E glass. The variation of the thermal performance between orientations ranged from 1 to 3% compared to 8.85% between east-facing and west-facing house in the base case.

CONCLUSION

This research has investigated the thermal optimization of windows components in relation to orientation in a representative governmental housing project in the UAE. The thermal performance of the dominant house type was first tested in relation to the cardinal orientation. The west facing house carried almost 9% more annual energy consumption than the east orientation. Then, single window components were tested for the energy savings potential. A vinyl frame with thermal break and three efficient glass alternatives were identified, and tested including: double reflective glass, double Low-E glass and double squared Low-E. The latter provided optimum performance with savings ranging from 3% to 8% of the total annual energy consumption, repectively for the east and west orientations while the vinyl frame with the original glass type yielded between 4% and 5% energy savings. Subsequently, the most effieicnt components were combined and tested. The double squared Low-E tinted glass and vinyl frame yielded savings ranging from 6 % to11.7% respectively for the east and west orientation. More importantly, the optimal window components highlighted similar performance independently from orientation, thus enabling flexibility in housing planning projects with increased thermal efficiency and energy savings.

ABSTRACT

Contemporary architecture has tended to increase envelope insulation levels in an unceasing effort to reduce U-values. Traditional masonry architecture in contrast was devoid of insulation, except for the inherent insulative nature of vernacular materials. Also the consistency of the outer membrane of the building skin diminished any impact due to bridging. In contemporary highly insulated walls bridges are numerous due to the necessity to bind inner and outer structural skins through insulation layers. This paper examines thermal bridging in an example of contemporary façade design and compares it with an example of traditional vernacular architecture currently being researched which is characterized by a lack of bridging elements. Focus is given to heavy weight materials of high thermal mass, which appropriately for passive architecture help moderate fluctuations in internal temperature. In an extensive experimental study samples of highly insulated precast concrete sandwich panels and lime rendered masonry walls are tested in a guarded hot-box. The building construction methods are compared for static and dynamic thermal transmittance, via heat flux and surface temperature differential measurements. Focus is given to the differential heat loss due to the thermal bridging in the sandwich panels and its associated impact on overall heat loss relative to traditional masonry construction.

INTRODUCTION

Building envelopes are becoming increasingly capable at retaining heat. European and national regulations are emphasizing ever-lower U-values, increasing pressure on building designers to augment the insulation content of walls so as to meet these targets.

Standard domestic construction is generally either of solid masonry wall, timber or steel frame construction. Focusing on solid wall construction, Stazi et al. (Stazi, Vegliò, Di Perna, & Munafò, 2013) define the 3 different wall construction categories common to temperate climates as (i) *capacity*, (ii) *stratification* and (iii) *resistance*. In Western Europe since mid 1900s cavity wall (*stratification*) construction has prevailed (Hens, Janssens, Depraetere, Carmeliet, & Lecompte, 2007). Prior to the postwar emphasis on cavity wall *stratified* construction, solid or *capacity* walls were common. Monolithic or rubble stone walls were common in vernacular construction, and still constitute the envelope of many farmhouse and cottage architecture in the European and Irish context. Today many of

Oliver Kinnane is Assistant Professor of Façade Engineering at the Dept. of Civil, Structural and Environmental Engineering. Trinity College Dublin. Sara Pavia is Associate Professor with a focus on sustainable building materials. Patrick O'Shea and Jennifer McGinn are MAI graduates from the class of 2014. John Grimes was an Research Assistant from 2013-2014.

this building stock is in need of thermal upgrade. Contemporary insulation materials trap moisture and prevent these traditional structures from 'breathing'. Novel alternatives based on natural, sustainable materials are required.

Today cavity walls are often in the 3rd category described by Stazi, *resistance*, given that many have been either retrofit with pumped interstitial insulation or augmented with a layer of internal or external insulation. Another type of *resistance* wall is the precast wall, or sandwich panel type. This construction type, which is becoming increasingly popular in Europe and is already well established in the tilt up construction market of the US, is endowed with the benefits of prefabrication which ensure time, cost and quality efficiencies of factory floor construction. In multi-story construction precast sandwich panels (PCSP) must be designed to ensure composite action between the interior and exterior concrete wythes. Lower U-values imply thicker insulation layer, which in turn implies larger tie elements, often metallic and hence highly conductive of heat. So even though specified U-values might be achievable using high levels of insulation, the thermal bridging impact of the ties becomes relatively more significant as the insulation gets thicker, a phenomenon now well established (Mao, 1997).

There are a number of reasons why PCSPs are specified (robust nature, finished surface etc.) but primary amongst these is their superior thermal mass properties over lightweight construction alternatives. They might be viewed as closer in thermal mass terms to traditional solid wall structures than to contemporary frame structures. They have a *capacity* likely to impact on the internal thermal environment however, the heat transmission to the outside is minimized due to the interstitial insulation layer. However, thermal bridges are numerous in PCSPs (Lee & Pessiki, 2006). Thermal bridging in contemporary facades has long been recognized as a significant failing in the *resistance* model of façade design with some authors claiming up to 30% of building heating requirements are given to façade thermal bridges (Theodosiou & Papadopoulos, 2008).

This paper investigates *R* and *U*-values in two wall construction methods. The construction types are disparate but enable exploration of the impact of thermal resistance and bridging in contemporary (insulation heavy) solid wall construction in contrast to a sustainable, vernacular-appropriate, alternative (with inherent insulation properties). These are compared and contrasted with past research in the literature that documents thermal bridging in other common construction methods, including frame construction. The theoretical *U*-values are compared with the real *U*-value calculated experimentally via hot-box testing procedure. The traditional envelope consists of an insulating lime-hemp render applied to the external of a solid brick masonry wall. Lime-hemp is under general research investigation by these researchers as an appropriate 'breathable' insulation method for historic building renovation. An example contemporary envelope is investigated via PCSP samples. These sandwich panels include significant insulation layers. Although the U-value when analysed both with and without the impact of thermal bridging is relatively low the relative impact of thermal bridging is significant and needs to be accounted for.

METHODOLOGY

Experimental and simulation studies were undertaken. The experimental program was based on five wall samples; (i) a solid clay-brick masonry wall bound with hemp-lime mortar, (ii) a lime-hemp (2:1 by mass ratio) render applied to (i), (iii) a lime-hemp (1:1.25 by mass ratio) render applied to (i), (iv) PCSP with 240mm insulation and 240mm deep, 3mm thick bridging plate, (v) PCSP with 160mm insulation and 80mm deep, 2mm thick bridging plate. The impact of the bridging plate was then investigated using a simplified Finite Element Model (FEM) that was developed.

Experimentation

A one-sided hot box is used to measure the total amount of heat transferred from one side of the specimen to the other for a given temperature difference, irrespective of the individual modes of heat transfer. The internal environment is tightly controlled (at 35°C) however the external environment vary with ambient indoor conditions. EN ISO 8990 and ASTM C1363-05 specify similar hot-box testing procedures and methods of heat exchange calculation. Neither consider the sample configuration but instead calculate the total heat transfer that passes through the sample under test based on recorded heat flux and temperature values (Asdrubali & Baldinelli, 2011). According to BS ISO 9869-1 data is taken for a minimum of 3 days for each heat flux recording and care is taken to choose days of minimal temperature variation. Samples taken every 10 minutes are averaged according to the average method described **by equation (1)**.

The steady state thermal resistance of the wall (R_t) can be calculated by,

$$R_t = \frac{\sum_{j=1}^{n}(T_{Sij}-T_{Soj})}{\sum_{j=1}^{n}(q_j)} = \frac{T_{Si}-T_{So}}{\emptyset/A} = \frac{\Delta T}{\emptyset/A}\ (m^2K/W) \quad (1)$$

where, T_{si} and T_{so} are inside and outside surface temperatures, ϕ is the heat flux over area A.

The R_t value is measured via experimental testing. To calculate the U values, standardized surface resistance on the inner and outer wall surfaces are added to R_t. These are given in EN ISO 6946 as R_{Si} = 0.13 m2 K/W and R_{So} = 0.04 m2 K/W in the case of horizontal heat flux (Martin, Campos-Celador, Escudero, Gómez, & Sala, 2012).

$$U = \frac{1}{R_T} = \frac{1}{R_{Si}+R_t+R_{So}} \quad (2)$$

The whole building heat loss might then be characterized (CIBSE Guide A, 2006) using the equation,

$$H_t = \sum AU + \sum L\psi \quad (3)$$

where, H_t is the whole building heat loss, A is the area of all surfaces, Ψ is the thermal bridge and L is its length of thermal bridges.

A number of methods of calculating thermal bridging in PCSPs with varying levels of accuracy have been proposed in the literature, as previously reviewed (O'Hegarty & Kinnane, 2012). For a 2D analysis Griffith et al (Griffith, Finlayson, Yazdanian, & Arasteh, 1997) present a THERM based parallel path method of U-value approximation that is adopted here. Given their depth to thickness ratio the bridging plates in this study might be approximated to propagate heat in the 2D plane. The parallel path U-value (U_p) is given by,

$$U_p = F_B U_B + F_N U_N \quad (4)$$

where F_B is the fraction of bridged section and F_N is the fraction of non-bridged section.

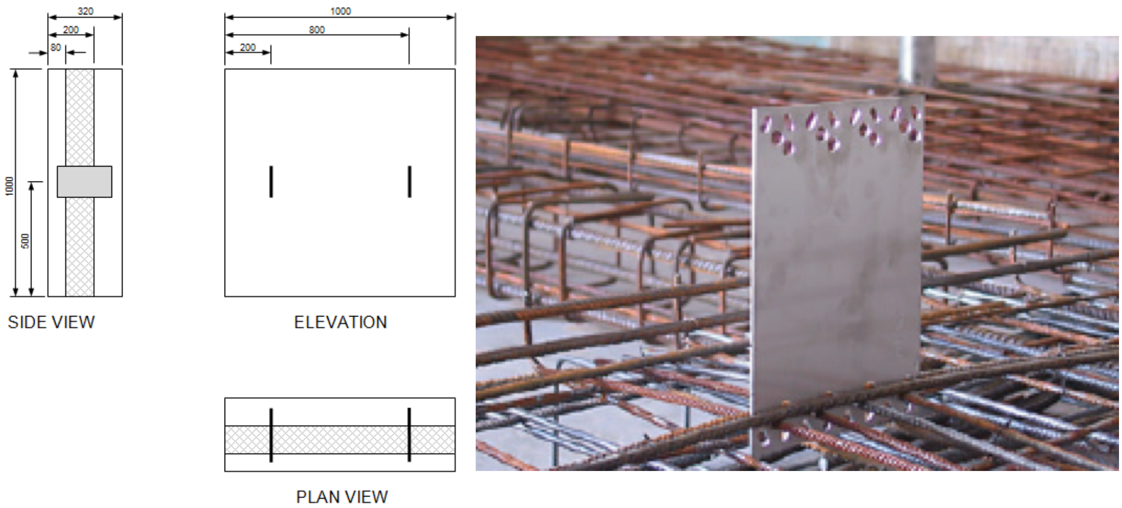
To further evaluate the effect of thermal bridging in the precast panels in this study a FEM was developed. The model was a simplified representation including concrete, insulation and plate geometry and properties, but without reinforcement detail.

Masonry Walls. Figure 1 shows the 1m x 1m brick masonry wall (**Figure 1 a)**) and lime-hemp render subsequently applied to one half of the wall (**Figure 1 b)**). A second and different mix is applied to the other half of the wall and both are monitored for heat loss (**Figure 1 c)**). No thermal bridging is evident in the 1m^2 section of masonry wall, and the lime-hemp render is homogenous over the complete surface of the wall. Two lime-hemp renders were investigated with different proportions. Mix 1 was based on the standard mix commonly used in industry – proportions 2:1, lime:hemp. Mix 2 reduced the lime content and increased the hemp content with the aim of achieving greater thermal insulation – proportions 1:1.25, lime:hemp. The brick is a filled-clay, machine-pressed brick, presoaked and bound with a Natural Hydraulic Lime 3.5 mortar. Approximate density and thermal conductivies are 1200 kg/m^3 and 0.36 W/mK respectively (CIBSE Guide A, 2006).

a) b) c) d)

Figure 1 a) Masonry brick wall, b) one half of wall rendered with lime-hemp render, c) heat flux probes and surface temperature sensors installed for hot-box testing, and d) infra-red image during testing.

Precast walls. Two precast concrete sandwich panels (1m x 1m) were tested in the guarded hot-box. An example panel configuration **is shown in Figure 2**. The exact plate and panel configuration **is given in** Table 2. The plates that are responsible for ensure composite action are also **shown in Figure 2**. These are threaded with reinforcement bar prior to casting. The exterior wythe of both panels is 100mm, the internal wythe which is structurally salient is 120mm. The wythe of insulation layer varies from 240mm in panel 1 to 160mm in panel 2. The insulation is Expanded Polystyrene (EPS) with thermal conductivity of 0.035 W/mK. Approximate density and thermal conductivy for concrete are 2200 kg/m^3 and 1.7 W/mK respectively (CIBSE Guide A, 2006).



a) b)

Figure 2 a) precast sandwich panel configuration, and b) example of plate tie used and method of attachment to rebar prior to casting of concrete.

RESULTS

Key results for the hot-box analysis of the brick masonry and PCSPs are documented in subsequent tables.

Masonry walls. The results of the hot-box and thermal resistance tests are presented **in Table 1**. The thermal benefit of adding the lime-hemp insulative render to different wall types is evident. The thermal resistance increases by approximately 50% with the addition of 21mm lime-hemp render layer.

Table 1. Experimental heat flux, *R* and *U*-values of the brick masonry with lime-hemp render

Wall construction	Heat Flux W/m^2	R-value m^2K/W	U-value W/m^2K
Brick and lime mortar	48.35	0.175	2.89
Brick and lime mortar with lime-hemp render (Mix 1)	36.5	0.259	2.33
Brick and lime mortar with hemp lime render (Mix 2)	37.74	0.274	2.25

The lime-hemp render can be seen to add an additional 0.084 m^2K/W and 0.1 m^2K/W to the bare brick masonry wall R-value.

Precast walls. Precast concrete sandwich panels were investigated for overall thermal resistance and for the effect of bridging. Aggregated results of hot-box tests for the two panels are described **in Table 1**.

Table 2. Key dimensional parameters and experimentally calculated heat flux, *R* and *U*-values of the precast concrete sandwich panels

Panel and Plate dimensions		Heat Flux W/m^2	R-value m^2K/W	U-value W/m^2K
Panel 1. Insulation width -240mm Plate width - 350mm	Plate thickness - 3mm Plate depth - 240mm	4.24	4.54	0.22
Panel 2. Insulation width -160mm Plate width - 260mm	Plate thickness - 2mm Plate depth - 80mm	4.69	3.13	0.33

Heat flux values are low in both PCSPs as might be expected given the considerable quantity of insulation within the panels. Panel 1 with 240mm insulation has a 45% greater thermal resistance than Panel 2 with 80mm extra insulation.

Table 3. Experimental evidence of thermal bridging due to plate connectors in precast sandwich panels

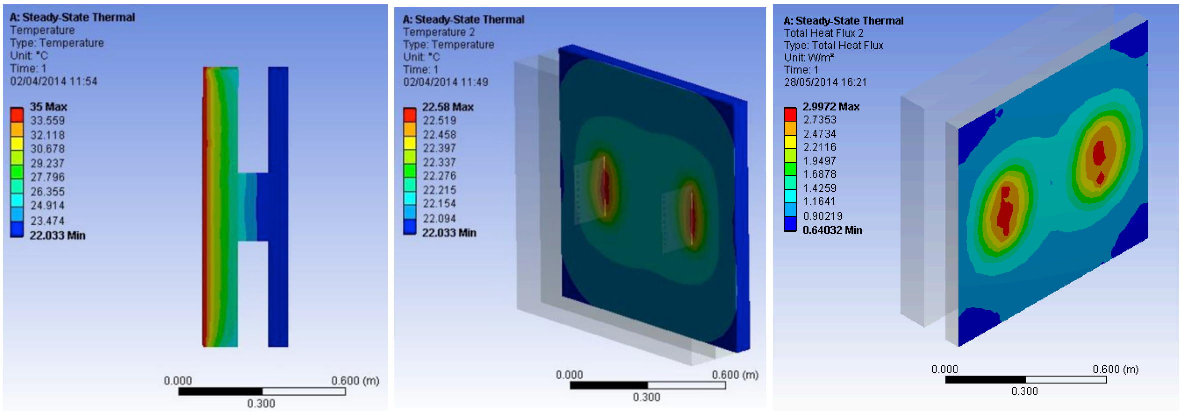
Panel and Plate bridge dimensions	U non-bridged location	U bridged location	U % locational difference
Panel 1.	0.22	0.45	104%
	0.33	0.49	48%

Panel 2.

The heat loss through the concrete surface is considerably greater at the location of the plates than over the centre. The plates are 55mm below the surface yet the heat flux increases from 4.24 to 10.46 W/m^2 in Panel 1 and 4.69 to 9.9 in Panel 2. The effect of bridging is relatively considerably more evident in Panel 1 than in Panel 2. This is due to the greater depth (240mm vs 80mm) and thickness (3mm vs 2mm) parameters of the plate.

A 240mm deep plate is 24% of the cross section of the panel, and an 80mm plate, 8%. Using the parallel method **equation (4)** the U-value for Panel 1 and Panel 2 can be corrected to 0.277 W/m^{2}K and 0.34 W/m^{2}K respectively, to account for the thermal bridging along the line of the panel.

Finite Element Model. Results of the FEM model of the precast concrete sandwich panel are shown in Figure 3. The steady state heat profile is shown in Figure 3(a) when the interior wythe of concrete is heated in a hot-box to 35^{o}C. The temperature at the internal face of the exterior wythe, on the other side of the insulation later, of the precast sandwich panel is as low as 23.7^{o}C. The model shows minimal temperature impact of thermal bridging on the panel with the outer face of the exterior wythe only fractionally higher (0.3^{o}C) than standard room temperature 22^{o}C.



a) b) c)

Figure 3 a) FEM thermal analysis (simulation of concrete wythe heated to 35^{o}C in a hot-box), (hot-box and insulation hidden in model). b) Isolated solution showing temperatures at interior face of external concrete wythe and, c) Heat flux through front surface of panel

CONCLUSIONS

This paper presents an experimental study of two solid walls, an example sustainable vernacular construction and an alternative highly insulated contemporary, solid wall constructions. Both constructions have their individual strenghts. In the vernacular construction, sustainable materials with less well recognized insulative ability are investigated. Brick and stone solid walls are characterized by low U-values, however introduction of the lime-hemp render layer enhances the thermal resistance of solid architecture construction by up to 16% in some cases, and 50% on the single leaf brick wall. Even with the addition of the lime-hemp render the thick vernacular masonry walls listed **in** Error! Reference ource not found. retain high *U*-values. However, given their lack of spot bridging, thermal capacity capability and recognized benefitial impact on the internal environmental conditions in appropriate climates (Martín, Mazarrón, & Cañas, 2010), traditional solid solid wall constructions retain advantages over contemporary façade systems. These walls are generally also devoid of thermal bridging.

In the example of solid but panelised contemporary wall construction, although the U-value of the wall is low due to a significant insulation layer, thermal bridging exists and effects the overall thermal performance. However, given the relatively small area over which it acts its impact is not seen as a considerable deficiency. Next stages in this research study involve analysis of the thermal mass effects of both wall types. The walls will behave differently in dynamic environments. The position of the insulation layer within the build up of the contemporary wall reduces the fluctuations in temperature that the sandwich panel wall will experience relative to a solid alternative.

The study is not without its limitations, and these are subsequently outlined. The hot-box used is somewhat more primative than that used in past studies – given that its made of four walls created by layering insulation panels - however it can offer approximate thermal resistance values. A limitation of the study is the impact of dynamic environmental conditions on the ambient air on the cold side of the hot-box. Although the surface temperatures vary in a very narrow range (~2-3°) relative to the ambient air temperature fluctuations (~5-6°). Another matter that should be noted is that the steady state modeling study returns lower heat flux values, of up to 33%, than the experimental study. The model does not capture the reinforcement bar and hence the conductive route of bars to plate is not modeled. The bars lie perpendicular to the plates, but contact them at a number of locations.

Further research aims to develop accurate models of thermal bridge in solid wall construction and to investigate alternative sustainable insulation materials. The transient effects of thermal bridging and its impact on thermal storage and diffusivity will be investigated through experimental and numerical simulation. This paper outlines some of the basis for this research by investigating examples of traditional, *capacity,* wall types, and contemporary, *resistance* wall types through an experimental steady state evaluation.

ABSTRACT

The absence of solar radiation at night gives good opportunities for passive cooling of buildings in hot climates with frequently clear sky. However the possibility of also taking advantage of a clear sky cooling potential during the day is seldom considered.

Thermal radiation to sky can be used to cool. A body surface emits thermal radiation (far IR) and if direct solar radiation (visible and near IR) and thermal radiation coming from other surfaces do not reach it, there would be a net heat flux out.

A previous prototype was done with a simple element. That experiment confirmed that was possible to reduce around two degrees the interior temperature of the test unit exposed to sun light in July.

In this work a new design based on the first one is developed to adapt it to architectonical needs in order to reduce interior spaces temperature in hot climates.

The aim of this design is focused to so an architectonical adaptation is needed. Modular and replicable units could be a solution that permits to fulfill large flat surfaces as roofs or other architectonic elements. In this occasion, measurements were taken from a modular model with a geometrical design that avoided de direct solar incidence. These measurements were taken by a pyrgeometer during two weeks of August and results were similar to the previous experiment.

INTRODUCTION

A body surface emits thermal radiation (far InfraRed, IR), and if it can be made that direct solar radiation (visible and near IR), and thermal radiation from other bodies (far IR) do not reach the body surface, there would be a net heat flux out of the body, cooling it (Head 1962). The cooling can be obtained by selective surfaces, that reflect visible and near infrared solar radiation (near IR), avoiding direct solar gains, while they are emitters for far infrared radiation, if they are appropriately exposed, and allowing radiation going to sky. Cooling can also be achieved with the help of reflective surfaces and geometry (Trombe 1967 and Hull 1986). A polished surface with high reflectance to infrared radiation is able to reflect the image of the sky and maintain the radiation characteristics (Granqvist 1982). An emitting surface "seeing" the reflected image of sky, will loss energy to the reflected part of cold sky (Craig et al. 2008).

The previous prototype tested in Barcelone was done with a single element (Serra et al. 2010). In that occasion, the analysis let us know that it is possible to reduce the inside temperature of a chamber, in about two degrees, during the sunny hours if an emitting surface can see nothing but the cold sky zone and its emitted radiation is thrown far away without reflection that take it back. That prototype checked the effect with a single element covering the entire top side of the box. The vertical development was very high and this dificults the practical applications in architecture.

In this work we consider the possibilities of irradiative cooling in Mediterranean climate for cooling interior spaces of buildings. We want to test a variant of the first model that incorporates the principle refrigerator to a replicable element that fill a flat roof being easy to construct and modular. The second main goal is about the system should use cheap, easily available materials in the existing industry such us aluminum foil and cardboard.

To face this challenge we have deepened the geometric study of the protection element of the emitting sheet, so that the surface occupied by the protection system was reasonable and the effective emitting area was the largest as possible. Geometry must help us to make that the emmiting surface only would see the cold zone of the sky even by reflection.

The emitting surfaces were white painted metal sheet as in the first model. In order to reduce thermal exchange with exterior air (Johnson 1975, and Golaka et al. 2007), we installed a thin 50 µm transparent polyethylene film 3 mm before the emitting surface. In this way the polyethylene film does not receive direct solar radiation and its life is expected to be longer because no significant UltraViolet (UV) radiation reaches the film. The test model was made with common materials and located in a village near the Mediterranean coast, and measurements were taken, by a pyrgeometer, during two weeks of August.

GEOMETRICAL APPROACH

Those two features, an easy construction and avoid IR radiation, can be both obtained if a suitable geometry for a lateral screen system is designed. We did a very detailed study of the geometry of the unit module. Such geometry should comply with the protection requirements of solar incidence both direct and reflected. The geometric study started from the solar path during the worst day -summer solstice- on a stereografic diagram, to narrow the sky zone without the sun passing throw, see Figure 1. Zones 1 and 2 on the diagram represent the coolest zone of celest voult, away both from the sun path and from the horizon, to avoid radiation emitted from extern objects that could reduce the net heat flux out from our emitting surface.

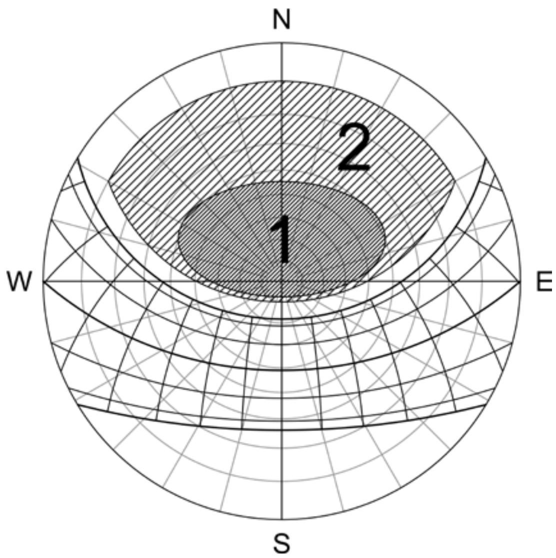

Figure 1 A stereographic diagram for Barcelona, near 41º north latitude. Zones 1 and 2 are preferred for thermal radiation exchanged. Zone 1 has lower equivalent radiant temperatures.

The vertex of a 134º opening cone, looking to the correct direction to the north for this latitude about 41º north, will never see the sun it sees the cold sky zone (see figure 2). We must place the emitting surface behind the initial vertex to obtain a large enough area for the irradiative surface, although this brings up a narrower conical element. So we extended the generatrices of the cone beyond the vertex looking for an ortogonal angle with the opposite sheed to avoid reflected rays coming back. Then we transformed the cone to a pyramidal piece because planar forms are more usefull to replicate and add elements. This choice should provide an eligible prototype for construction useful to add units in order to fulfill a roof.

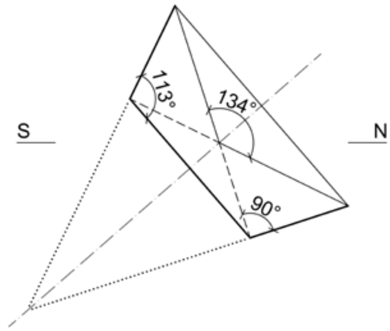

Figure 2 The diagram shows the overture of the first conical unit element with an overture of 134º toward the cold zone of the sky, and the geometrical definition of the replicable pyramidal unit.

Finally the side flaps were extended to protect the interior of possible radiation reflected in them and even folds were we calculated graphically the correct angle to improve the efficiency of the global suitable surface. Lateral slopes in contact to the emitting surface respond to the pyramid design explained above, bottom slope was further worked in order to maximize the efficiency. Its tilt was modified in the far part because the high of incident solar rays in that point was minor and if we fold it back we can reduce the occupied roof area by each basical unit (see figure 3).

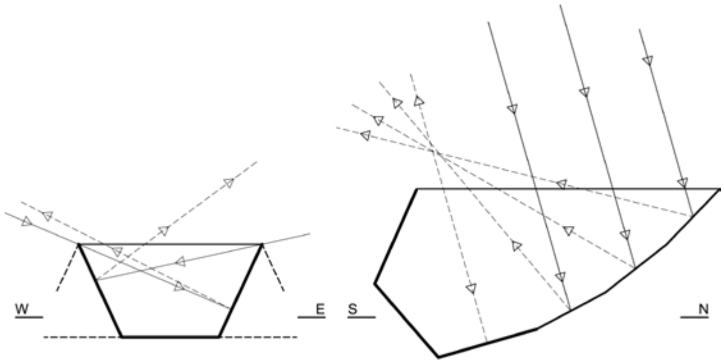

Figure 3 Shows the two sections of the basical unit and the reflected sun rays of sun on the side screens. Folding the northen screen reduces the ratio between emiting surface and global roof surface.

Different units can be easily aggregated. Some faces are extended in order to cover the horizontal roof with high performance. Lateral extreme screens are also extended to avoid sunlight entering during the first and last hours of the summer days. As a result of this process, we obtain a geometric model with an effective surface area of 1/6 of total roof area.

PROTOTIPE AND MESUREMENTS

The roof model was installed on a 50cmx50cmx30cm box, with 7 cm of expanded polystyrene thermal insulation, see figure 4.

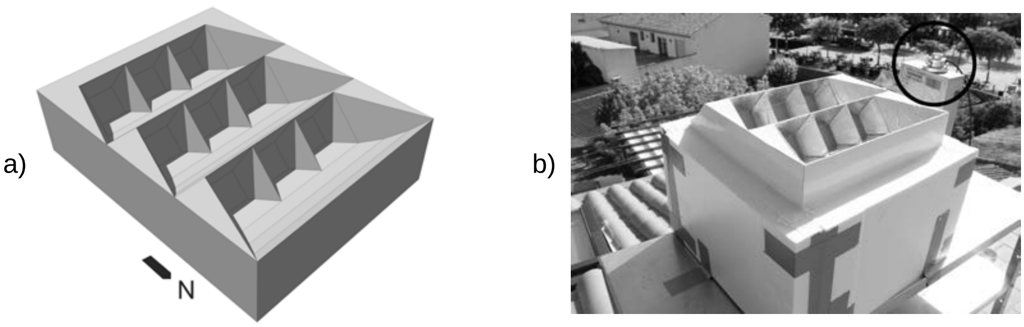

Figure 4. a) Digital 3D model. b) Photograph of the built prototype. The circle shows the pyrgeometer.

The emitting surfaces were white painted metal sheet. In order to reduce thermal exchange with exterior air (Tazawa 1996, and Tazawa 1997), we installed a thin 50 µm transparent polyethylene film 3 mm before the emitting surface. In this way the polyethylene film does not receive direct solar radiation and its life is expected to be longer because no significant UV radiation reaches the film.

The model has been checked during a period of sunny days of August, in a roof of a house in Sant Llorenç del Penedés (near Barcelona).

Measures of thermal emission have been done with a Pyrgeometer 1239 from Hukseflux thermal sensors with a Cambell Scientific datalogger 21538, and compared with solar radiation from a Pyranometer at the automatic meteorological station (XEMA 2013) placed in El Vendrell (5 km from the scale model). Both devices measure total (direct and diffused) radiation in different wavelengths.

The obtained results for the modular case show that during some sunlight hours the interior temperature is higher than exterior temperature.

The figure 5 shows the measured solar radiation and the thermal radiation emitted to the sky. The average of received solar radiation is higher than emitted thermal radiation. The emitted is relatively low due to the Mediterranean Sea influence, because of meteorological reasons (dominant South component winds from the sea, in summer, and large evaporation of water). Relatively high humidity (near 67% with mean temperature near 26ºC) lowers the cooling radiation effect, because the opacity of water vapors to IR radiation. However, according to the measurements from the Pyrgeometer, it should be pointed out that even in this case, it is possible to emit near 100 W/m^2 to the sky.

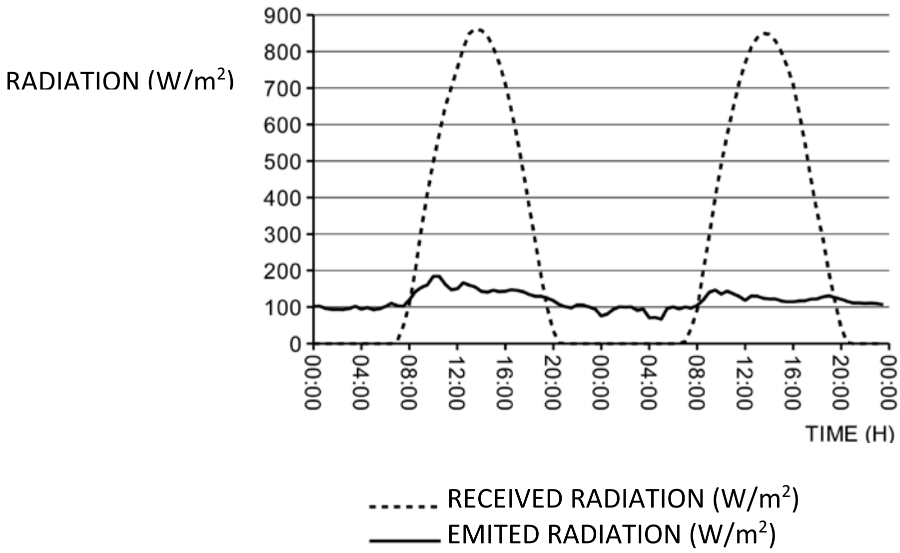

Figure 5 Dotted line shows global solar radiation on horizontal surface from meteorological station. Continuous line shows net IR radiation emitted to the sky from the Pyrgeometer

With the above data and the exterior temperature we computed a thermal balance equation for the interior of the model. We take into account the exterior air temperature, the thickness of the thermal insulation, the thermal radiation from the emitting surfaces, a heat transfer from the sun exposed sides of the model (surface temperature measured with a 66 IR Thermometer from FLUKE) and an approach to the diffuse radiation on the roof.

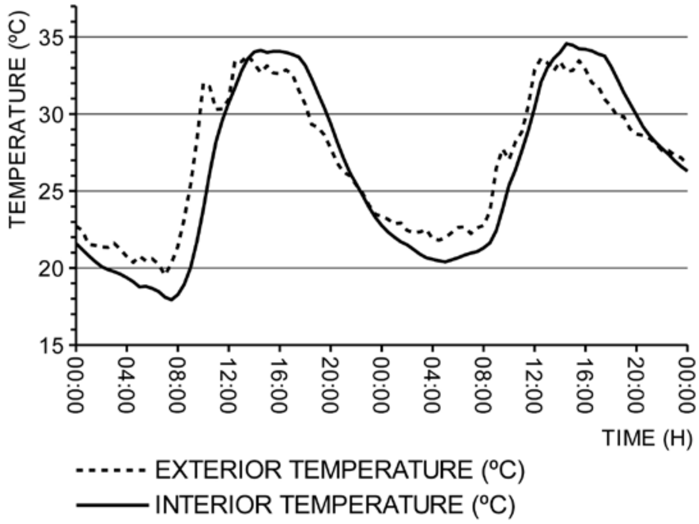

Figure 5 Dotted line shows the exterior temperature and continuos line the interior one.

The measured interior temperatures at 14h are no more than 0.3ºC different from those calculated by this approach. An excessive entrance of heat due to direct solar radiation incidence on the model area increases exterior surface temperatures. A high value of diffuse radiation conditions of Mediterranean summer sky also contributes to reduce the efficiency of this prototype as cooling device.

If solar protection had been applied to the lateral walls of the modular system, as it was done in the first model, the computation result would be 1.3 ºC lower. In this case, the interior temperature would be lower than external temperature during almost all day. Further on, an increase of roof thermal insulation in the parts which receive direct sunlight could have improved the results.

CONCLUSION

We consider two prototypes of radiative cooling roof. First one is a simple unit where the whole roof acts as IR emitting surface and lateral protections to direct sunlight are added. Second one is a modular design where the emitting surface is 1/6 of the roof area because of the integrated sunlight protections.

In both cases the space to be cooled was near 40x40x30 cm and was thermally insulated with at least 5 cm of expanded polystyrene except for the emitting surfaces.

First prototype was tested in Barcelona and the measured interior temperature was near 2ºC lower than exterior. This result is in agreement with a basic calculation taking into account heat transfer trough the walls and thermal emission from the roof. Exterior surfaces of the model were at exterior air temperature because they were protected from direct solar radiation.

In the second case the interior temperature was 2.5ºC lower than exterior only during night hours, while it was near 2.5ºC higher than temperature during some sunlight hours. This result can be understood because of solar gains through the sunlit walls and indirect solar radiation gains through the roof. The measured interior temperatures at 14h are no more than 0.3ºC different from those calculated by the thermal balance equation. If solar protection had been applied to the lateral walls of the modular system, as it was done in the first model, the result would have been better.

Summarizing, the possibilities of diurnal radiative cooling during summer in Mediterranean climate are mainly bounded by three factors. First of them is the relatively high humidity and low transparence of atmosphere to IR radiation. However, according to the measurements from the Pyrgeometer, it should be pointed out that it is possible to emit near 100 W/m^2 to the sky in our summer climate. Second one is the need to restrict, with an appropriate geometry, the aperture of the radiating system to the cold zone of the sky vault. And third factor is the absolute need to reduce the entrance of direct or diffuse solar radiation. Even with these bounds, we show that it is possible to obtain diurnal radiative cooling in sunny places by appropriate selection of geometry and easy to obtain materials.

ABSTRACT

The rapidly urbanizing environment and resultant social and environmental impacts are far too complex and significant to limit problem-solving capacity to one discipline. Collaboration will become increasingly imperative in our increasingly dynamic world, yet despite the demands on designers, planners, engineers and developers; there remains a lack of collaboration and critical analysis on how we integrate the built environment within its larger context. Popular "green" building programs are increasingly being adopted for improving environmental impact on a project-by-project basis, focusing on building systems and materiality. However, ecosystems function on a landscape level and guidelines and design consideration at that spatial scale are lacking. The result is a landscape that is relegated to left over spaces. Despite their lack of attention, these interstitial, remnant exterior spaces in our growing cities can have meaningful contributions aesthetically, ecologically and socially and should be given more thought in the design process through collaboration.

To highlight the contributions these small spaces can make, a research project where ecosystem services (stormwater, habitat value, soil health and social implications) are measured and its application to a master plan for a sub-urban Greenfield Institutional site in Nairobi will be discussed. This design approach reflects the growing trend in landscape architecture, which focuses on "evidence-based" design (Brown and Corry, 2011). By measuring and monitoring the contributions a landscape can make, designers can fully engage the site to maximize its performance and create an integrated, interactive and adaptive relationship between people, buildings and their environment. These case studies will clarify the significant and once underestimated contributions that mechanically simple and biologically complex living systems above and below ground can make to stormwater management and habitat quality, and the social implications of these beautiful, legible and high-performance landscapes.

INTRODUCTION

Designing a landscape that maximizes ecosystem services, along with human health and well-being, requires the disciplines of natural sciences, architecture, urban design and landscape architecture to engage in research and outreach to support the amelioration of our urban environments through "evidence-based" design (Brown and Corry, 2011). Scientists and designers need to pursue rigorous research on designed systems to understand their contributions related to aesthetic and social values, and functional ecosystem services. Additionally, the research must not only look at designed landscape projects, but also at natural analogous systems for setting performance and sustainability benchmarks. When designing urban landscape spaces to maximize social, ecological, economic and aesthetic benefits, designers must set measurable goals.

This paper explores the growing yet relatively new field of performance-based landscapes, from design to post-occupancy research, within an urban context by focusing on The University of Pennsylvania's Shoemaker Green project. The preliminary findings from the data collections of this project has ratified the framework developed for quantifying the success of an integrated ecological design process; a process that has been crafted over the last five decades or so by the ecological design and planning community. Al Jamea Tus Saifiyah educational campus in Nairobi which adopted this integrated process in embedding environmental resiliency into the development of a greenfield Institutional site in Nairobi, can be a model for rapidly urbanizing cities across the globe. While the contexts of the two projects discussed here are vastly different, engaging in the reinvention and revitalization of the site through an understanding of its larger context and systems, remains an underlying consistent theme.

Figure 1 Two examples of landscapes that are benchmarks for providing ecosystem services: Sidwell Friends School in Washington D.C., where the constructed wetland becomes a "working landscape" using biological processes to clean grey and black water (left) and Phipps Conservatory in Pittsburgh which has achieved "living building challenge" rating (right). Both sites are currently being monitored for ecosystem services.

SHOEMAKER GREEN CASE STUDY

As a SITES[1] pilot project, the goals of the 2.75 acre Shoemaker Green project were to improve water, soil, vegetation, materials, human health and well-being in unison. Each component played a vital role in creating a healthy functioning ecological system. A monitoring plan (2012-2017) was established with the University to measure the performance of the site. The measurement was primarily focused on stormwater management performance through installed green infrastructure features that included sand filters, rain gardens, bio-swales, tree trenches and cisterns, etc. The goal of monitoring is intended to inform the SITES performance benchmarks, the City of Philadelphia and other regulatory entities such as the Environmental Protection Agency (EPA) that sets standards for environmental impacts of projects across the United States.

Figure 2 Shoemaker site plan and photograph of the site showing an event on the Green.

SHOEMAKER GREEN MONITORING PROTOCOL, PROJECT OBSERVATIONS AND PRELIMINARY FINDINGS

Establishing measurable goals requires a multidimensional investigation that involves observing comparable sites where these dimensions have been measured and by looking to analogous natural systems, which can serve as benchmarks for high performance. Understanding the interaction between abiotic and biotic parts of a landscape resulting in maximum performance and embedding resiliency in design that deals with unforeseen factors in unpredictable and harsh urban environments, becomes a quite daunting, but essential component of sustainable landscape design of urban spaces. Unfortunately, data on comparable landscapes that measure similar parameters is lacking, but reasonable amounts of information about performance of our natural systems are available.

The Shoemaker Green design team looked at one of the most high performing terrestrial models; the eastern deciduous forest, specifically the forests of the Delaware River Terrace and the Piedmont Upland Ecoregions; to inform the critical design components of the project's efficient, high performance landscapes. Given the specific issues relevant to the City of Philadelphia and the site's proximity to the City's river corridors, the focus of landscape performance was centered on stormwater management and habitat value. This inquiry required a comprehensive study of analogous forest characteristics--vegetation assemblages, soil structure, habitat creation and the possible human role in these systems. The monitoring program was structured to test the design hypotheses. As such, data related to stormwater, transpiration, soil, habitat diversity and social behavior were analyzed by scientifically accepted methods.

Stormwater Quantity and Quality- Every drop of rain water and a portion of air conditioning condensate from surrounding buildings is routed through a matrix of plants and soil and various conveyance systems, such as swales, trench drains and smart drains into a 20,000 gallon underground cistern (Figure 3). From May 2013 to September 2014, data shows that no stormwater has left the system to the combined sewer, including a 3.16-inch storm in June 2013 and 11 unusually wet months of the 14 month monitoring period. . Increased residence time (detention) within vegetated systems also allows more opportunity for water to be transpired and evaporated, which is especially beneficial in urban areas that are prone to heat island effect. On two occasions the system came close to overflowing on a dry day and a malfunctioning irrigation system was the key contributor (Figure 4). These findings allowed the facilities managers to adjust the irrigation program and modify it to be more efficient.

Figure 3 Stormwater features include a stormwater sand-based storage system under the Green (upper left and right), a rain garden (lower left) and a 20,000 gallon cistern (bottom right) for water reuse.

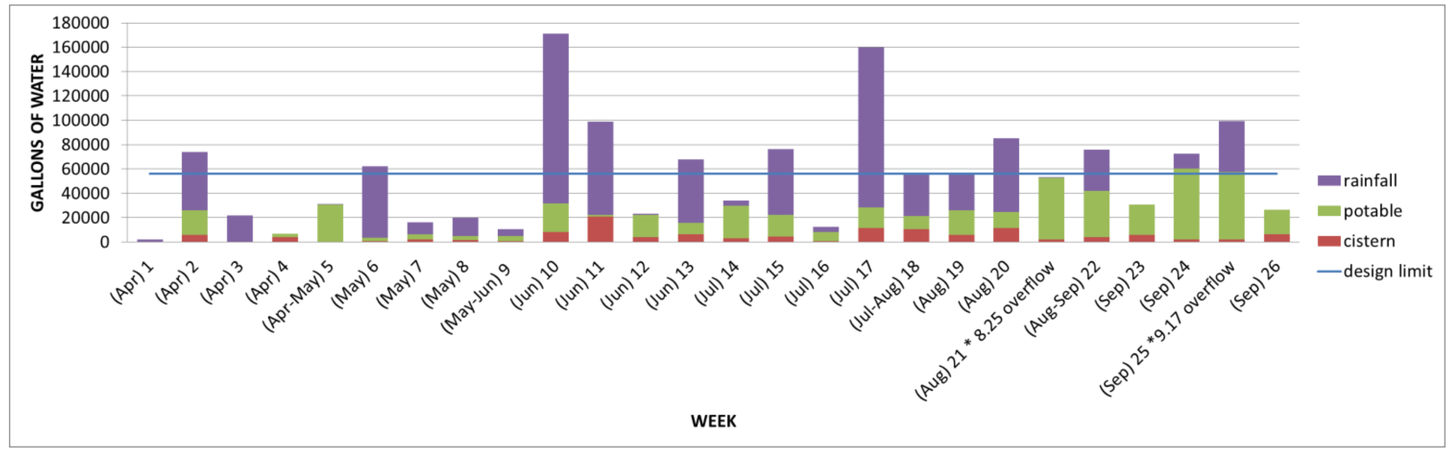

Figure 4 Irrigation use and rainfall data for 2013. Overflow to the combined sewer only happened twice.

Transpiration- Transpiration was monitored using leaf area index (LAI) values that were calculated with a linear photosynthetically active radiation (PAR) sensor and a leaf porometer. Data were gathered from trees, shrubs and groundcovers. The transpiration rates (E, mmol m−2 s−1) of leaves were calculated from the stomatal conductance and meteorological data gathered from the on-site weather station using Fick's law and the Penman – Monteith equation (Rahman et al., 2011). Preliminary results indicate strong transpiration rates from *Quercus phellos* and *Nyssa sylvatica* (Figure 5, left). A strong performance by the native floodplain species in the urban forest parallels that of the native forest studies, giving an insight into species that may be successful for transpiration within urban settings. (Beissel and Shear, 1997). This data was paired with soil evaporation measurements taken from the site's tensiometers to understand the water loss through evapotranspiration.

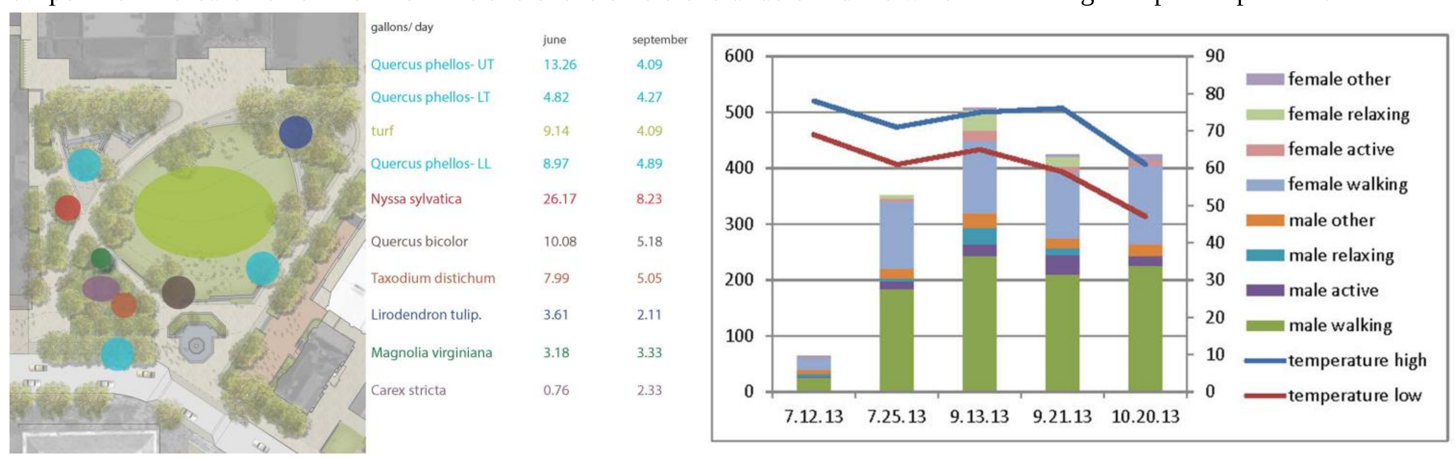

Figure 5 Transpiration rates of tree species taken over 3 different months in 2013 (left) and example of social mapping conducted July through September 2013 (right).

Soil- Preliminary data indicates microorganisms are present and the soils are developing organic matter to the desired levels suitable for different landscape types. However, compaction readings indicate that some areas of the lawn (four of the seven sampling points) are slowly approaching the 300psi threshold, which is the compaction rate when roots begin to resist penetration. In the rain garden, soil reports indicate a balanced fungal to bacteria ratio, a ratio expected in a landscape that supports healthy perennial grasses and understory trees; and few indicators of anaerobic conditions, suggesting that the rain garden is currently "drying out" between wet periods.

Habitat- One migratory species that is found regularly throughout shrubby thickets and woods, particularly along watercourses and in wetlands in North America is the yellow warbler, *Septophaga petechial*. The warbler, rarely found in urban settings, was spotted in the *Carex stricta* in the rain garden gleaning insects, suggesting the beginning of a diverse urban habitat. Other species identified include: Song Sparrow (visual ID), House Sparrow (visual ID) and a Wood Thrush (vocal ID).

Social Mapping- The social impact of the site is currently being studied through surveys and behavior mapping. The surveys were distributed to 200 randomly selected visitors in February, March and April of 2014. Visitor utilization was also documented via behavior mapping observation (Figure 5, right). From the surveys, it was evident that the extensive use of the space, as observed through each season, and the perceived value of the space, indicates an opportunity for education that can encourage an appreciation for urban ecological systems. Also, very early findings suggest that designed pathways were appropriately sized for the foot traffic and further analysis is needed to better understand the social implications of the project.

APPLICATION OF RESEARCH TO AL JAMEA TUS SAIFIYAH CAMPUS MASTER PLAN IN NAIROBI, KENYA

An ecological design approach and a collaborative process, one which carefully interweaves environmental and sustainable design principles, was adopted for planning the new Al Jamea Tus Saifiyah educational campus in Nairobi; a campus planned to reflect Fatemi cultural concepts, Fatemi philosophy, art and architecture, while utilizing state-of-the-art modern technologies and the latest educational thinking to provide enhanced ecosystem services. The Shoemaker Green research framework for monitoring the performance of the landscapes on the site has been used to develop a site specific ecosystem monitoring dashboard for the Jamea site. The monitoring program will measure microclimate benefits, irrigation use, stormwater volume and quality and species diversity on identified test plots within the nine acres of gardens and green roofs.

Figure 6 Site Plan of Al Jamea Tus Saifiyah Campus, Nairobi showing integration of buildings with open space.

Evaluating the context and site conditions, along with understanding the nature and ecology specific to the site, led to site specific solutions that will be sustainable over the long term. Close collaboration between the client and the design team helped achieve the goals of re-introducing biodiversity, enhancing the site's ecological systems, creating landscapes that are self-maintaining and more resilient to climate extremes, while using minimum energy and human capital. The confluence of ideas that emerged from the study of patterns of native analogous vegetation; the microtopography; flora and the fauna; the movement of the sun and temperature swings; wind and its seasonal changes; and the fluctuations in rainfall were useful in setting up a monitoring protocol for measuring the ecosystem services after the completion of construction in 2015.

Sustainable water features are integrated in the design to capture run-off and enhance campus microclimate. Runoff directed through plant beds, vegetated buffers and rain gardens improves water quality while reducing portable water use for irrigation. Heating and cooling effects of the green roof compared to the landscape at grade will be measured using sensors and heat transducers placed at all layers of the roofing, above the plants, and above the green roof area. Stormwater run-off volume and quantity overflow from the green roof, collected in the cisterns, and the volume leaving the site will be measured. Bordering the Nairobi National Park, the Site's context is characterized as semi-humid to semi-arid and offers an opportunity to extend the natural wildlife habitat by creating ecological corridors. Multi-layer native plant assemblages are re-introduced within the site based on lessons in ecological structure and diversity provided by the native plant communities. Biological monitoring involving study of species present including microbial activity, micro fauna and fauna will be recorded for a period of 2 years. Healthy Soils are essential to vigorous plant growth, effective stormwater management and reducing landscape maintenance. The soils on the site are deep, friable black cotton soils over rock which are flood prone, nutrient poor and have high shrink-swell capacity. The existing soil quality will be enhanced using borrowed fill from a neighboring construction site, incorporating mychorrhizae and compost from the on-site composting facility.

INFERENCES AND CONCLUSION

The preliminary results from the Shoemaker Green project and the other projects being currently monitored, are starting to provide a scientific backing to the hypothesis that landscapes and their biotic components provide critical ecosystem services, and that maintenance and monitoring are important for the long term sustainability of any project. Even a relatively small urban landscape, is capable of fulfilling multiple aesthetic, social and environmental roles. While there remains much more to learn from ongoing monitoring of Shoemaker and other projects, it is clear is that the success of the integrated design process is dependent on including maintenance and monitoring as a part of a comprehensive design of our landscapes. As designers we should collectively ask questions—ranging from investigations about the animals that pollinate and disperse the vegetation, to the mychorrhizae that help the trees and other vegetation manage stress and synthesize nutrients, and to the humans that care and maintain these spaces. Native and adapted plant communities that have adapted to unique environmental conditions and are surviving in dense urban scenarios can serve as models for setting the benchmark for ecosystem contribution. This exploration has tremendous applications in societies where the pressure of rapid development had the tendency to relegate landscape to left over spaces. Embedding resiliency and creating high performance landscapes, irrespective of size, is our opportunity to reclaim lost "ground".

ABSTRACT

Most modern houses no longer use traditional heating systems (e.g., the fireplace, stove, the pechka, the ondol, and the kotatsu) and instead rely on mechanical heaters, as the latter have greater functionality and more features. However, as the traditional systems use wood, a natural energy resource, they are more suitable for reducing the consumption of fossil fuels. Further, they provide a unique sensation of warmth as they dissipate heat through thermal radiation.

In this study, in order to reevaluate the heating characteristics of traditional heating systems that use wood, we devised a new method for measuring their thermal radiation properties. On the basis of the concept of the luminous intensity distribution, we defined the "thermal radiant intensity distribution," which is calculated by integrating the luminance of thermal radiation in each direction. A thermal image is constructed by assembling pixels representing the surface temperatures determined from a parallel projection of the heating equipment. Hence, the luminance of thermal radiation could be found for all the directions from the pixels to the observer.

We employed the proposed method to investigate a large firewood stove in operation in the winter, and determined its thermal radiant intensity, which was found to be 47–121 W/sr; this value is much greater than that of an electric heater (an 800 W electric heater has a thermal radiant intensity of 15 W/sr). It was assumed that, as traditional heating systems do not include a fan, larger systems are installed within the building structure and warm not only the air with the rooms but also the room surfaces, such as the walls, floors, and ceilings.

INTRODUCTION

In most modern houses, traditional heating equipment (e.g., the fireplace and stove in European countries, the *pechka* in Russia, the ondol in Korea, and the kotatsu in Japan) has been replaced by mechanical appliances such as air conditioners and fan heaters because of their better functionality and useful features. However, as traditional equipment use wood-based biomass, including firewood and wood charcoal, which are natural energy resources, they hold more potential in the near future from the view point of reducing fossil fuel use. Further, they also provide a unique sensation of warmth, owing to thermal radiation. For example, just after the Great East Japan Earthquake in 2011, firewood stoves were in high demand, especially in the arenas where the refugees lived for a few months in the winter season.

Masanori Sugawara is an associate professor in the Faculty of Education, Miyagi University of Education, Sendai, Japan. Tsukidate Toshiei is a professor in the Department of Civil Engineering and Architecture, Hachinohe Institute of Technology, Hachinohe, Japan. Wang YunXiao is a graduate student in the Graduate School of Education, Miyagi University of Education, Sendai, Japan.

The reason for this was not that the supply of other fuels was limited but rather that the heating capability of the stoves was better. It is for this reason that we have chosen to investigate the thermal radiation properties of traditional heating equipment.

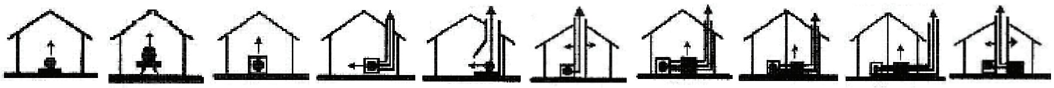
Figure 1 Firewood piled up under the eave of a traditional Japanese house.

1. EXOTHERMIC CHARACTERISTICS OF TRADITIONAL HEATING EQUIPMENT

Takamiya et al. have classified the heating equipment installed in vernacular architecture in Eurasia into Types #1 to #12 on the basis of their design characteristics, including factors such as whether the hearth is enclosed, where the exothermic part (i.e., the area, device, or unit from which the heat emitted) is located, whether it has a chimney, and what is its relation to the building. Developing this idea a little further, we have added the method of heat transfer to the classification system and reordered the types, deleting Types #6 and #7, as shown in Table 1.

With respect to the heating capability, Types #2 and #3 produce lower amounts of heat because these equipment pieces are "movable" and can be located in different places in the house, depending on the conditions. The "unified" types are graded from Type #1 to Type #12, that is, from "open" to "closed" on the enclosure of the hearth and "just around the hearth" to "dedicated part (in the next room)" on the exothermic part; these heaters are greater in size and have higher efficiencies. All the types except for Type #10 either do not have chimney or have an indoor one. Further, for all equipment types, heat transfer occurs through "radiation" or "conduction." Modern mechanical heaters, which are small and high-powered in comparison, distribute heat by blowing warm air in the room. As traditional heating systems do not include a fan, larger pieces of equipment are usually installed within the building structure to warm not only the air in the rooms but also the room surfaces, such as the walls, floors, and ceilings.

Table 1. Types and Characteristics of Heating Equipment

Type	#1	#2	#3	#5	#4	#8	#9	#11	#10	#12
										


Heater	Open hearth	Brazier	Kotatsu	Stove	Fire-place	*Pechka*	Kang	*Kachel-ofen*	Ondol	Kang
Enclosure of the hearth	<---- Open ---->		<--- Closed --->		Semi-Closed	<------------------- Closed ------------------->				
Part of the exothermic	<----------- Just around the hearth ----------->					Chim-ney	Dedi-cated part	Dedicated part in the next room		
Chimney	<--- Without chimney --->			<------------------- Indoors ------------------->					Out-doors	Indoors
Relation to building	Unified	<-- Movable -->		Fixed	<------------------------ Unified ------------------------>					
Method of heat transfer	<-- Radiation -->		Convection and Radiation		Radia-tion	Convec-tion and Radia-tion	<- Conduction ->		Convection, Radiation, and Conduction	

2. METHOD FOR EVALUATING THERMAL RADIATION PROPERTIES USING INFRARED THERMOGRAPHY

2.1 Thermal imaging

To determine the warmth-producing abilities of traditional pieces of heating equipment that make use of radiation and conduction rather than convection for heat transfer, as mentioned in Chapter 1, where the concept of luminous intensity (cd(= lm/sr)) distribution was described, we calculated their "thermal radiant intensity (W/sr) distributions." The thermal radiant intensity distribution of a heating system is a thermal radiation property and is obtained by integrating the luminance of thermal radiation (W/(sr m^2)) in every direction. The thermal radiant intensity for a specific direction is measured as follows:

1. Obtain thermal images using an infrared thermography system (i.e., a thermocamera) from a position at a specific distance from the center of the target heater. The nearer one is to the heater, the more detailed is the image obtained. However, if one is too near, the image will be distorted, in contrast to the image obtained from a parallel projection, because of the wide visual angle. However, it is difficult to keep the object distance large when photographing in the up/down directions. To ensure that the entire target heater was in the eyeshot of the thermocamera (horizontally 21.7° × vertically 16.4°) and to maintain the object distance at a reasonable value, we set it to 1.5 m.
2. Photograph the front side and in all the directions of the horizontal/vertical sides in steps of 22.5°. That is to say, photograph in 16 directions for each aspect, for a total of 41 directions (= (16 × 3) – 6 – 1), while excluding the 6 duplicated intersections and the upward view from below. If the shape of the heater is symmetric, it is enough to photograph 28 directions (= 41 – 1 – (3 × 4)).
3. Project the image of the concentric circles and radial lines on a wall of the room in which the photographs are being taken. Set the thermocamera at the intersection of these lines to pinpoint the object distance and the photography direction. We projected only one-fourth of the concentric circles (see Figure 2). Changing the top/bottom and the right/left directions allowed us to take photographs in limited space.

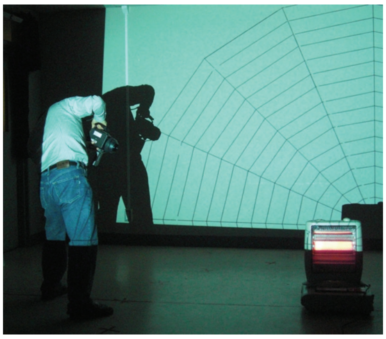


Figure 2 Procedure for obtaining the thermal image: the thermocamera is located at an object distance of 1.5 m; this can be confirmed from the shadow on the wall.

2.2 Calculating the thermal radiant intensity

If one considers a thermal image as a set of the surface temperature data that is the parallel projection of a heater, the thermal radiant intensity (W/sr) can be obtained by summing the luminance of the thermal radiation (W/(sr m^2)) from each pixel of the thermal image of the entire target heater to the observer, that is, in the direction normal to the thermal image (see Equation (1)). The denominator "2π" in Equation (1) represents the whole solid angle (sr) of the thermally imaged surface.

$$E = \sum_i \frac{\sigma T_i^4 S_i}{2\pi} \qquad (1)$$

3. MEASUREMENT OF THERMAL RADIATION PROPERTIES OF A LARGE FIREWOOD STOVE

3.1 Background for proposing a novel measurement method

The method described in Chapter 2 for measuring the thermal radiation properties has the following limitations:

1. It requires that the heater to be imaged be placed at a certain distance so that the entire heater fits in the eyeshot of the thermocamera.
2. The directions for which we can measure the thermal radiation properties using thermocamera are limited.

However, most traditional heating systems are large. Therefore, using this method, it is not possible to evaluate the thermal radiation properties in smaller houses as well as one can in the case of large houses.

3.2 From thermal imaging to thermal solid figures

Using the photogrammetry software "SurveyFromPhoto," it is possible to construct thermal solid figures from thermal images. We constructed thermal figures using bitmapped images with a 256-value palette. A heater and its thermal solid figure are shown in Figures 3 and 4, respectively. When constructing the thermal figures, the following four steps have to be followed, as per the specifications of SurveyFromPhoto. It should be noted that a thermal image has fewer pixels and colors than does an optical image. That is to say, it does not seem to have a third dimension.

1. The target can be photographed at any distance and from any direction and position. However, SurveyFromPhoto requires that each image has more than ten identity points. Further, among these, more than four of the identity points should be enclosed in several different images.
2. Before photographing the heater, place a piece of aluminum on any sharp edge or protrusion on the body of the heater so that its shape is visible and the identity points can be set with precision. Then, photograph the heater against a background of a different temperature.
3. Take photographs from each direction in front of the aluminum piece so that the identity points are distributed stereoscopically, as this will allow a precise solid figure to be constructed.
4. Take photographs from each direction in front of the major plane so that distortion-free images can be obtained to form the polygons that are used to construct the solid figure.

Figures 3 and 4 Photograph of the investigated electric heater (power of 800W) and its thermal solid figure.

3.3 Calculating the thermal radiant intensity

To calculate the thermal radiant intensity, Equation (1) can be used, provided the area of the pixels is determined as follows:

1. Push the PrtScn key on the keyboard when a thermal solid figure is displayed in the direction in which the thermal radiant intensity is to calculated, and open a copy of the image in the GNU Image Manipulation Program (GIMP).
2. Count the number of the pixels corresponding to the length of the reference line indicated in the image, and calculate the area of a single pixel (m^2) using Equation (2).
3. Erase all the pixels from the image, except those representing the target heater, either using the "fuzzy select" function of GIMP or manually (i.e., erase the pixels one by one), if necessary.
4. Save the image, which is now of only the target heater, in the BMP format and convert it to the CSV format using the software BMP2CSV, which allows one to change data formats.
5. Open the CSV file in Excel. The temperatures corresponding to the individual pixels can be found from the values in the spreadsheet and the color scale of the thermal image.

$$S = L^2 / N^2 \qquad (2)$$

3.4 Characteristics of the measurement method

When using the measurement method described in Chapter 2, the amount of thermal radiation emanating from the heating equipment is measured directly. Therefore, we can determine the actual values. On the other hand, in the case of the method described above, a thermal solid figure constructed using a software program is used as a virtual heater and is used for the measurements. Therefore, one can call the former method a direct one and the latter an indirect one.

The differences between the direct and indirect methods are listed in Table 2. The advantages of the indirect method are that the object distance and direction can be changed freely when taking the photographs. This makes it possible to photograph heaters in small rooms quickly. There are also a few disadvantages in than a number of different software programs are needed for the calculations. It should be noted that the distance for calculating the thermal radiant intensity, which is correlated to area of the pixels, is finite in the direct method, in which it is considered the object distance. On the other hand, it is infinite in the indirect method because the image constructed using SurveyFromPhoto is based on orthogonal projections. There is also a difference in the metric used to determine the size of the heating equipment. The solid angle (sr) is used in the direct method, while the projection area (m^2) is employed in the indirect method. Hence, it may be said that the two methods are quite different.

Table 2. Comparison of the direct and indirect measurement methods

Method	Direct	Indirect
Target for measuring thermal radiant intensity	Heating equipment	Thermal solid figure built using a software program and used as a virtual heater
Object distance	Distance at which the entire target heater fits in the eyeshot of the thermocamera	Actual distance, which depends on the space available in the room
Direction of photography	Direction of measurement	Actual direction for constructing the thermal solid figure
Software	NS9200 (NEC) Excel (Microsoft)	NS9200 (NEC) Excel (Microsoft) SurveyFromPhoto (Freeware) GIMP (Freeware) BMP2CSV (Freeware)

Distance for calculating the thermal radiant intensity	Finite	Infinite
Metric used to describe the size of the heating equipment	Solid angle	Projection area

3.5 Comparison of the results obtained using the direct and indirect methods

Figure 5 shows the thermal radiant intensities of the heater shown in Figure 3 as measured using the direct and indirect methods. The solid angle and thermal radiant intensity/solid angle ratio determined using the direct method, as well as the projection area and luminance of thermal radiation are also shown in the figure.

On comparing the thermal radiant intensity distributions obtained using the two methods, it was found that the distributions had similar shapes (oval) on the elevation side. However, the directions of the peaks on the sectional and horizontal sides were different. The maximum intensity was noticed in front of the heater, that is, at #13 in Figure 5, when using the direct method, while a gap of 22.5° or 45° existed when using the indirect method. This is because the grille and fire back do not affect the results obtained using the indirect method. That is to say, an exact heating element was not built in the virtual thermal solid figure but was represented by a thermal image plane instead. The difference in the thermal radiant intensities obtained using the two methods was less than 1.5 W/sr (i.e., 17%).

Further, on comparing the parallel values, that is, the thermal radiant intensity/solid angle ratio obtained using the direct method and the luminance of thermal radiation determined using the indirect method, the directions of the maximum/minimum values were similar. Thus, it can be surmised that the indirect method is suitable one.

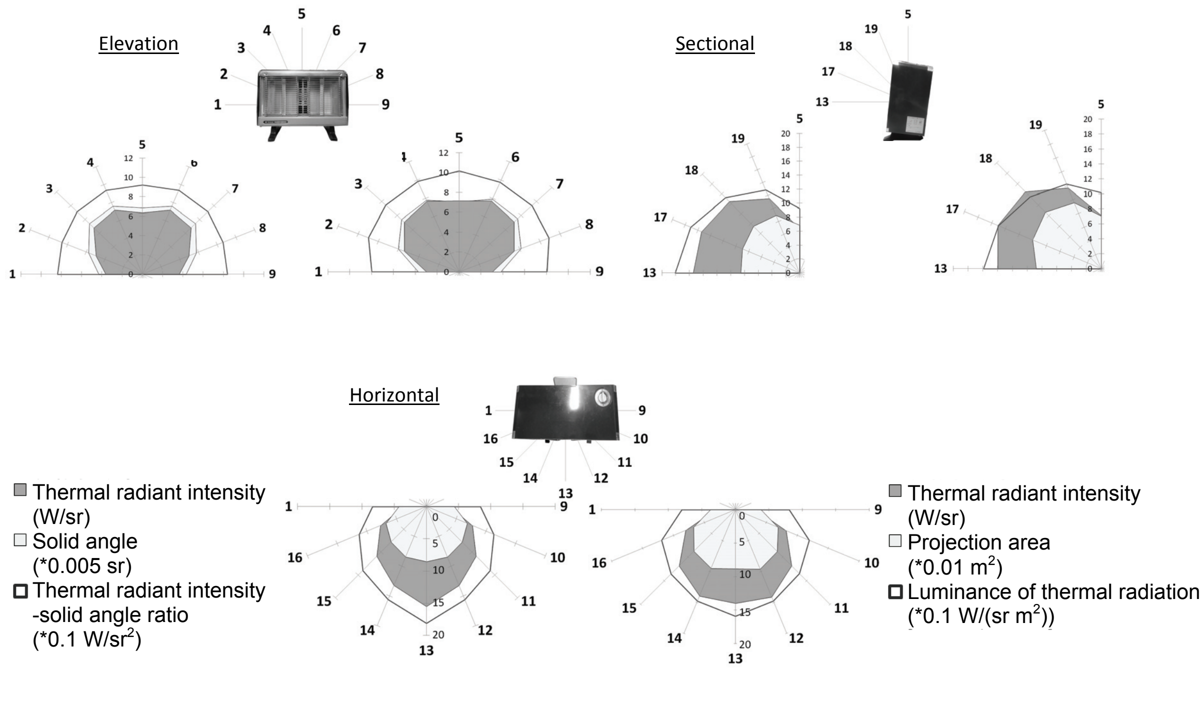

Figure 5 Comparison of the results obtained using the direct method (left) and the indirect method (right).

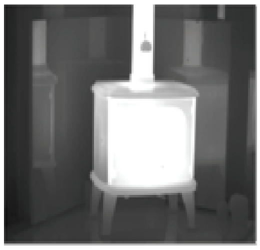
3.6 Thermal radiation properties of a large firewood stove

3.6.1 Measurement procedure. We employed the indirect method to measure the thermal radiation properties of a large firewood stove used routinely in the house. The target stove had a well-designed but complicated shape, as shown in Figure 6. The measurement was performed under the conditions listed in Table 3. Several kinds of air-dried firewood, such as Japanese cedar, cherry, sawtooth oak, and zelkova, to name a few, but not pine, were burned as per usual use. As can be seen from the thermal image in Figure 7, the surface temperature of almost the entire stove exceeded the upper limit of the range of the thermo camera (120 °C). Even though the stove was installed in a large room of a detached Japanese house, it was in a corner surrounded by houseplants and pieces of furniture. Therefore, the area that could be photographed was restricted.

3.6.2 Measurement results. The thermal radiant intensity, projection area, and luminance of thermal radiation of the large firewood stove are shown in Figure 8. The most important point to note is that the thermal radiant intensity was determined to be 47–121 W/sr, which is much greater than that of an electric heater (an 800 W electric heater exhibits a thermal radiant intensity of 15 W/sr). The main reason for this is that the entire surface of a stove is an exothermic area, and a large stove has a large area. Because the upper limit of the temperature range of the thermocamera was 120 °C, the thermal image obtained could not have indicated higher temperatures. However, if one assumes that the internal temperature of the stove was 200 °C, the thermal radiant intensity would be more than 2.1 times higher, as per Equation (1).



Figures 6 and 7 Photograph of the investigated large firewood stove (made of cast metal; width = 742 mm, thickness = 607 mm, and height = 797 mm; maximum power = 14.0 kW, as listed in the catalog) and one of its thermal images.

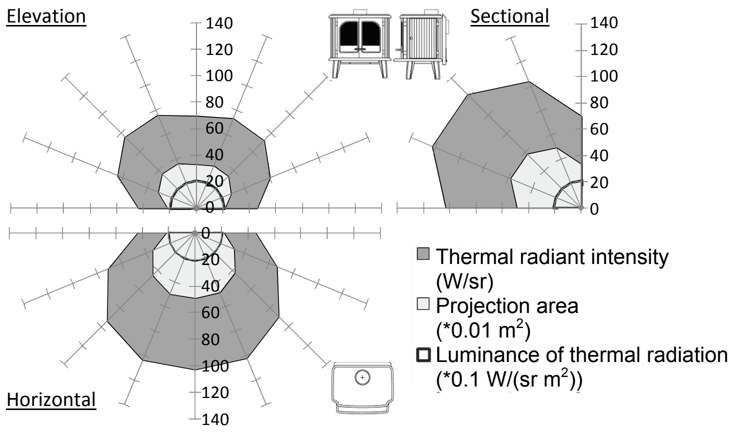


Figure 8 Thermal radiation characteristics of the large firewood stove.

Table 3. Measurement conditions

Date and time	Weather	Location	Indoor air temperature and relative humidity	Outdoor air temperature and relative humidity	Area of the room
Jan 26, 2011 10:30 AM to 12:00 PM	Fine	Detached house in Sendai, Japan	22.4 °C, 43% on average	6.2 °C, 42% on average	Main room with wellhole: 45.8 m^2

CONCLUSION

In this study, we proposed direct and indirect methods for measuring the thermal radiation properties of traditional heating equipment. Using the indirect method, we measured the thermal radiant intensity distribution of a large firewood stove and found that it radiated a large amount of thermal radiation. Shukuya has noted that *using radiant warm exergy for heating purposes is more effective than using convective warm exergy as the former results in both greater thermal comfort and a low human-body exergy consumption rate*. It is likely that the exergy consumption rate is a function of the quality of the warmth. The high thermal radiant intensity of the stove allowed it to not only warm the air in the room but also the room surfaces, such as the walls, floors, and ceilings. This probably accounts for the uniqueness of the warmth generated by traditional heating equipment. An exploration of type of walls and ceiling finishes should lead to a better understanding on how living spaces are heated through heat reflection/convection. We intend to pursue these goals in a future study.

ACKNOWLEDGEMENTS

We wish to express our gratitude to Ms. Hitomi Oba, Ms. Maki Ooka, and Ms. Rieko Matsumoto for their assistance and helpful suggestions. We also thank Mr. Hara for providing us with an improved version of SurveyFromPhoto, and Ms. Midori Hayasaka and Mr. Ko Kamata for offering a place to measure. This work was supported by a Grant-in-Aid for Scientific Research (KAKENHI) (No. 26560031) from the Japan Society for the Promotion of Science (JSPS).

NOMENCLATURE

E = thermal radiant intensity (W/sr)
L = length of reference line (m)
N = number of pixels corresponding to the length of reference line

ABSTRACT HEADING

We report a case study on the conversion into a Nearly Zero Energy Building (NZEB) of an existing building, "The Visitors Centre for Nature Interpretation "located in the Pyrenees mountains of Catalonia, Spain. The original building was constructed in the last decade using strategies of passive and low energy buildings. At that time, there were no regulations about energetic certification in our country, and we have no reliable information about the energetic performance of many modern buildings theoretically considered as "low energy".

The research was carried out by collecting data on real consumption and CO2 emissions values and analysing both the energy systems and the passive conception of the building. Afterwards, our conclusions furnished information on which to choose the strategies aiming at the energetic refurbishment and the conversion into nearly NZEB of this public centre.

The main finding is that, by applying a combination of refurbishment options and improving the energy systems, a saving of approximately 50% is achievable in energy use and carbon emissions. Due the optimal levels of solar radiation in this place, the rest of the energy needed to afford the NZEB goal can be supplied by a photovoltaic installation placed on the roof. This approach can be applied to inspire and inform future reconversions of the existing modern buildings in Catalonia into NZEBs.

INTRODUCTION

The building sector is one of the productive sectors that needs to be acted upon if what is sought is a drastic reduction in CO_2 emissions. As such, adapting existing buildings to future energy requirements, as provided for in the EU's Energy Performance of Buildings Directive (2010/31/EU), is a challenge that must be addressed if we hope to deal with pressing issues of global warming and climate change. To achieve these objectives, the EU Directive urges Member States to ensure that as of 31 December 2020 all new buildings in the European Union (or 2018 in the case of public administration buildings) should satisfy nearly zero energy standards. Nearly zero energy buildings (NZEBs) can be defined briefly as buildings with a very high level of energy efficiency, whose very low energy requirements should be met by energy from renewable sources, so that the balance between energy consumption and energy production is zero. However the EU Directive says nothing about existing buildings, which constitute the majority of the built heritage in use, and it seems likely that in the EU, because of the economic crisis, very few new buildings will actually be built in the coming years. Therefore, the real challenge is how to address the energy performance of the existing built heritage.

This paper summarises the applied research carried out by our research unit in which the use of specific software tools is of great importance for verifying the performance of solutions developed, in the first instance, intuitively

INTENT AND OBJECTIVES OF THE APPLIED RESEARCH

The building analyzed in this case study is the Visitors Centre for Nature Interpretation located in Son, a small village in the Pyrenees mountains in Catalonia (Spain). It lies at latitude 42º 37' N, longitude 1º 05' E and at an altitude of 1540 m. Based on the Köppen climate classification, Son occupies climate zone Dfb, characterized by mild summers and severe winters receiving snow in winter and constant rainfall throughout the rest of the year, exceeding 750 mm per annum. Average annual temperatures range between minus 10 and 25 ºC, and relative humidity between 65 and 100% in the summer and between 80 and 100% the rest of the year. The solar insolation index is high at around 4211 Wh/m2day, average, with a predominance of light winds from the west and south-west all the year.

The building was constructed during the last decade using passive design strategies in a highly valued environmental site located on the edge of the Aigüestortes National Park (Fig. 1).

Based on data accumulated over the period of more than ten years in which the building has been in use, we performed a diagnosis of the existing building collating data on its energy consumption and emissions. Our study proposes a series of actions aimed at achieving the standards of low-energy buildings, maximizing the active use of renewable energy and enhancing comfort conditions. All in all, the actions seek to minimize the building's environmental impact and so contribute, in some small way, to the global reduction in greenhouse gas emissions. In short, we seek to transform the Visitors Center into a nearly zero energy building.

The measures we took can be categorized in three types, implemented as follows:

1. Minimizing energy demand by enhancing the building's energy performance: Increasing insulation, improving solar radiation control and natural lighting and exploiting enhanced ventilation for cooling in the summer.
2. Increasing energy efficiency and improving the building management systems.
3. Substituting conventional energy sources with renewable sources.

The subsequent economic evaluation enabled us to analyze the feasibility of these measures and their payback period.

.

EVALUATION OF THE PRESENT BUILDING

The main conclusions to be drawn from the bioclimatic and energetic analyses of the building can be summed up as follows:

- The building is poorly insulated, and have thermal bridges. The openings are simple with many air leakage.
- The openings in the building's eaves block solar radiation in the summer and boost solar uptake in winter, but do not avoid penetration during warmer spring and autumn days.
- The building's orientation and design protects it from the prevailing westerly winds and impede natural ventilation.
- The levels of natural lighting are poor in communal areas during the day (bathrooms and corridors) and the levels and distribution of natural lighting in spaces with large openings to the exterior are not homogenous.
- Poor natural lighting necessitates the use of artificial lighting in many areas and is responsible for high electricity consumption.
- The building requires some cooling loads which currently remain unsatisfied with either passive or active systems.
- The building uses propane gas as its primary energy source, which is responsible for its high CO_2 emissions.

The total energy consumption of the building has been summarised in Table 1.

Figure 1 The Visitors Centre for Nature Interpretation

Table 1. Monthly data for electricity consumption

Month	Electricity consumptiom	Month	Electricity consumption
January*	---------------	July	12830,13 kWh
February*	9064,00 kWh	August	14196,82 kWh
March	17310,92 kWh	September	11826,03 kWh
April	13955,56 kWh	October	14753,26 kWh
May	10086,99 kWh	November	14640,30 kWh
June	13132,75 kWh	December*	7660,42 kWh
TOTAL			139458,00 kWh

*The visitors centre is closed from December 15 to February 15

Table 2. Annual energy consumption and CO_2 emissions

Primary source	Annual energy consumption	Conversion in kWh	Annual emissions CO_2	
Electricity	136.829 kWh	136.829 kWh	0,25 kgCO2eq/kWh*	34,2 Tn
Electricity - Photovoltaic	2.629 kWh	2.629 kWh	0	0 Tn
Propane gas	23.314 kg	324.512 kWh	2,94 kgCO2eq/kg	68,5 Tn
Diesel	10.577 l	26.500 kWh	2,72 kgCO2eq/l	28,8 Tn
Solar Thermal	15.194 kWh	15.194 kWh	0	0 Tn
	TOTAL	**505.664 kWh**	**TOTAL**	**131,5 Tn**
	Ratio (kWh/m2year)	202	Ratio (kg/m2year)	53

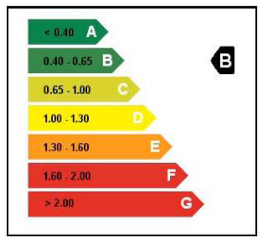
For assessing the CO_2 emissions, we have taken into account the annual energy consumption from different sources and emission coefficients per unit (Table 2)

ENERGY CERTIFICATION OF THE CURRENT BUILDING

A simulation was conducted with Leader and Calener software (Table 3) providing the following results: the building has a significant heating load (G) that can be attributed to the area's climatic conditions and a significant cooling load (C). Its CO2 emissions are average, being awarded a D, which is some way off the optimum level (A).
According to Spanish regulations the building's energy certification is graded as a B and the environmental conditions achieved inside the building must be: 23ºC - 25ºC temperature / 45% -60% relative humidity range in sumer and 21ªC-23ªC temperature / 40%-50% relative humidity range in winter.

Table 3. Energy certification

3. ETIQUETA Y VALORES TOTALES



Concepto	Edif. Objeto	Edif. Referencia

El consumo real de energía del edificio y sus emisiones de dióxido de carbono dependerán de la climatología y de las condiciones de operación y funcionamiento reales del edificio, entre otros factores.

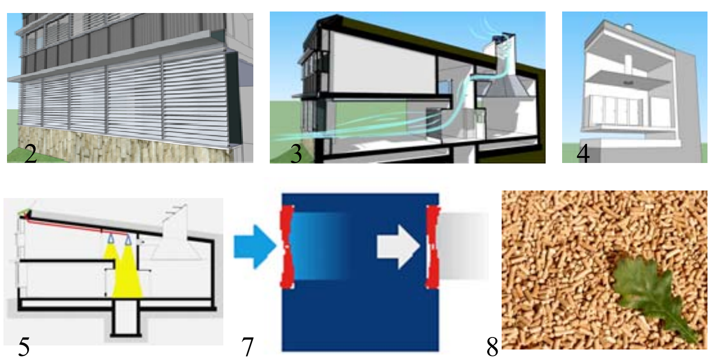
ACTION CHECK LIST

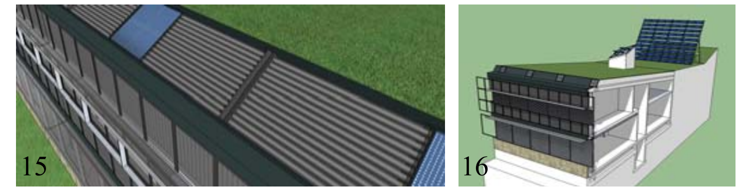
This section describes the actions planned to reduce the building energy consumption and achieve Nearly Zero Energy Building while improving indoor environmental quality. Will also detail the software tools that have been used for energy modeling.

Improvements employing passive strategies

1. Increasing wall insulation and replacement of existing windows by Higher-efficiency windows
2. Installation of motorized venetian blinds for protection from solar radiation on the south-facing façade (simulation with Ecotec)
3. Improving natural ventilation system for cooling in the summer (simulation with Phoenics)
4. Installation of highly efficient light tubes for channeling natural lighting into the bathrooms
5. Installation of a solar collector for channeling natural lighting in the corridors

Figure 2 Improvements



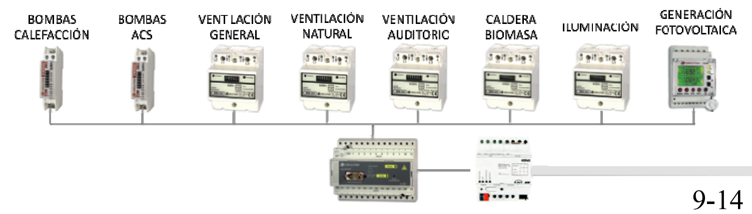


Improvements based on energy efficient systems

6. Optimization of artificial lighting by adjusting power installments (simulation with Dialux)
7. Installation of free cooling system in the auditorium
8. Replacement of gas boiler with a biomass boiler for heating and air conditioning

Enhancing the equipment of the building's management systems to increase energy efficiency

9. Control and regulation of blinds
10. Control and regulation of natural ventilation
11. Regulation system for lighting and light levels
12. Control and regulation of the free cooling system in the auditorium
13. System of measurement and monitoring of power consumption
14. System management of all the proposed services



9-14

Substitution of conventional energy sources with renewable sources

15. Production of air conditioning with solar thermal vacuum tubes, (48 modules, 62,48 m2. of catchment)
16. Electricity production using a photovoltaic installation on the roof, (78,75 kWp)

While it is evident that to increase energy efficiency of the building, the first action should be to improve the insulation, in some well-designed buildings of our modern built heritage like this one, specific constructive solutions to improve thermal performance of the building envelope are very difficult to implement, due to its high cost and the modification of its image. Therefore in this particular case study it was decided to use other strategies that do not damage the outward appearance and the interior finishes

ENERGY BALANCE

Among the different actions proposed we have included a new primary energy source, namely, biomass. Propane gas and diesel consumption has been virtually eliminated, limited now solely to the kitchen. We have not taken into consideration the fuel used in the electric generator as consumption is restricted to exceptional occasions (when there is a power outage) and so this does not form part of the building's normal operating conditions. The building's electricity consumption has undergone a significant reduction (in the order of 37%), which has considerably improved the ratio of energy consumed per square meter/year.

CO_2 EMISSIONS

Taking into account the reductions in consumption outlined in the previous section (and ignoring fuel consumption for the reasons presented above), the CO2 emissions can now be assessed. The electrical energy harvested from the photovoltaic system makes a negative contribution to CO2 emissions because it is clean energy fed into the grid, which helps improve the energy mix. This output also improves the ratio of energy consumed per square meter, as it offsets a significant proportion of the total, reducing the ratio from 202 kWh/m2 to 131 kWh/m2 year in the initial year of the proposed scenario.

Without taking the photovoltaic system into consideration, CO2 emissions are significantly reduced from an initial 302 tons/year to 131.5 tons/year, thanks to the marked reduction in the total amount of electricity consumption and virtual elimination of propane gas consumption. If we consider the total energy harvested from the photovoltaic system, we see this generates all the electricity consumed, thus enabling us to certify our building as a net zero energy building.

Energy consumption and CO2 emissions are summarized in Table 4.

Table 4. Final annual energy consumption and CO_2 emissions

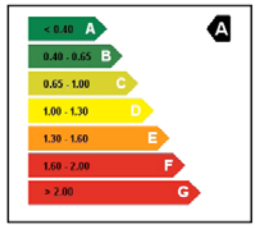
Primary source	Annual energy consumption	Conversion in kWh	Annual emissions CO_2	
Electricity	105.313 kWh	105.313 kWh	0,25 kgCO2eq/kWh*	20,3 Tn
Electricity - Photovoltaic	-119.640 kWh	-119.640 kWh	0,25 kgCO2eq/kWh*	-29,9 Tn
Gas propane	1.314 kg	1.290 kWh	2,94 kgCO2eq/kg	3,9 Tn
Biomass	80.213 kg	300.800 kWh	Balance neutral	0 Tn
Solar Thermal	38.913 kWh	38.913 kWh	0	0 Tn
	TOTAL	**326.676 kWh**	**TOTAL**	**0,3 Tn**
	Ratio (kWh/m2year)	131	Ratio (kg/m2year)	0

FINAL ENERGY CERTIFICATION

After implementing the above actions a new simulation was conducted with the Leader and Calener software providing the following results: improvements in the passive design mean that the load demand has been reduced by 10%. The use of energy efficient active systems and the harvesting of energy from renewable sources now ensure the provision of 100% of the uilding's requirements. In this respect, the building's initial D rating has been raised to an A.

Table 5. Final energy certification

3. ETIQUETA Y VALORES TOTALES



Concepto	Edif. Objeto	Edif. Referencia
Energía Final (kWh/año)	81346.2	810075.3
Energía Final (kWh/(m²año))	53.8	536.0
En. Primaria (kWh/año)	0.0	2053487.8
En. Primaria (kWh/(m²año))	0.0	1358.6
Emisiones (kg CO2/año)	**0.0**	**612624.5**
Emisiones (kg CO2/(m²año))	**0.0**	**339.2**

El consumo real de energía del edificio y sus emisiones de dióxido de carbono dependerán de la climatología y de las condiciones de operación y funcionamiento reales del edificio, entre otros factores.

Production of ACS using vacuum tubes also satisfies 100% of demand.

Improvements in artificial lighting mean the building's initial B rating has been raised to a final A rating. CO2 emissions have been reduced to a minimum. The building obtains a final A rating, recording optimum scores in all categories.

INFERENCES AND CONCLUSION

Table 6. Actions, quality improvements, saving and investment

Improvements	Annual quantitative improvements: Decrease emissions Tn CO2/year		Savings/year		Investment	
Louvers (installation and regulation)					114.217 €	14,5 %
Natural ventilation (installation and regulation)					103.420 €	13.2 %
Natural lighting bathrooms	0,18 Tn CO_2	0,2 %	110 €	0,2 %	5.018 €	0,6 %
Natural lighting hallways	3,65 Tn CO_2	3,3 %	2.187 €	3,9 %	67.811 €	8,6 %
Lighting (control and regulation)	13,46 Tn CO_2	12,2 %	8.078 €	14,3 %	23.518 €	3,0 %
Auditory cooling (installation and regulation)					39.170 €	5,0 %
Biomass Boiler	56,85 Tn CO_2	51,4 %	12.682 €	22,5%	39.865 €	5,1 %
Solar Thermal Energy	4,40 Tn CO_2	4,0 %	2.215 €	3,9 %	55.959 €	7,1 %
Photovoltaic energy	29,9 Tn CO_2	27,1 %	29.910 €	53,1 %	327.994 €	41,7 %
Electrical lines losses reduction	1,98 Tn CO_2	1,8 %	1.189 €	2,1 %	6.497 €	0,8 %
Electrical consumption measurement					2.729 €	0,3 %
Total	110,42 Tn CO_2	100 %	56.371 €	100 %	786.198 €	100 %

In a not too distant future, the progressive implementation of the Energy Performance of Buildings Directive in the building sector will lead a transition to the design of new buildings in which the energy concept constitutes a fundamental premise. This clearly represents a major challenge for architects, radically changing the way we design buildings.

This paper has made various contributions to this debate. In terms of methodology, it has stressed the importance of using specific software tools to verify the behavior of the solutions proposed. As shown with the corresponding architectural modifications, any existing building can achieve the nearly zero energy standards and produce its energy requirements from renewable sources in the building or in its surrounding environment. The building in our case study today generates 100% of its energy. This is a clear example of energy efficient architecture employing the tools of the bioclimatic design process. Active energy efficiency and the use of renewable energy sources are the way to shrink a building's carbon footprint.

Finally, we conclude that the most useful contributions of our applied research lie, first, in its ability to inspire and lead architects and engineers in the future energetic refurbishment of built heritage as they convert them into NZEBs. This proposal is a practical demonstration that sustainability is not an obstacle to design but rather a challenge to creativity. And, second, our proposal has the ability to revive those productive sectors suffering the effects of the current economic crisis. The example reported here should reduce resistance within the construction sector to adopt these principles, thereby allowing a successful theoretical concept to become a reality that can be accepted by the market and so generate renewed economic activity.

ACKNOWLEDGMENTS REFERENCES

This applied research has been developed by C-06239 Agreement between the Polytechnic University of Catalonia and "fundacio territori i paisatge" It has enjoyed the cooperation of the students of the Master Architecture and Sustainability Carles Carreras, Juli Fernandez, Anré Lopes, Midory Monroy, Alvaro Quiroga, that under our leadership have developed graphical approach, drawing plans and renderings, and thus have greatly helped us in the development of this proposal.

ABSTRACT

*Energy efficiency's specialized bibliographic sources define phantom loads as a dispensable electric energy inversion that some appliances make on secondary functions, such as light's pilots, remote control receptors and digital clocks. This investigation was developed in the "Laboratorio de Estudios y Experimentación Técnica en Arquitectura", LEET (Technical Experiments, of the Universidad Pontificia Bolivariana Architecture School, FAD-UPB). It proposes the verification, analysis and quantification of the phantom loads in residential buildings located on Medellin, Colombia, emphasizing on its origins based on the kind of appliances, its technologic validity and the use factor. The applied methodology on this investigation was based on energy consumption measurements during the stand-by mode of all the appliances of eleven similar socioeconomic condition residential buildings. A wattmeter was used as the main measurement tool. The results of this investigation revealed on quantitative data the impact of phantom loads over the total electric energy consumption bill of the analyzed buildings. Results also allowed classification of phantom loads according to how much the energy leak is, and its use. Consolidated data of this investigation prove that phantom loads are **3.73%** of the total electric consumption. This represents an opportunity of finding alternatives for an efficient management model of the cities electric consumption. This paper's conclusions are the first approach to the energy leaking problem in the national context.*

Keywords: *phantom loads, energy conservation, electricity, sustainable house.*

INTRODUCTION

Invention of the incandescent lamp in the year 1860 by English chemist Joseph Swan (*National Museum of American History*), defined the beginning of a process of colonization of households by technology that favored, during the following years, the invention of several electrical appliances, such as the telephone, the radio, the television set and the oven, among many others. During the decade of 1970, advances were carried out in the field of electronics: the personal computer was invented, as well as video games, cell phones and Internet. For all human needs that arose, a non-manual device was created to solve it, and that automatization process of daily household life known as automation, foresaw times of a high demand for electric energy.

Simultaneously to techonological advancement in the twentieth century, there emerged under the general ignorance, a phenomenon related to the electric energy consumption: "phantom loads" or "ghost loads". Since the invention of the remote control in 1903, some household electronic devices used it as the main command, which adaptation to radios and television sets required a new operational mode to

Author A is. Author B is.

use household devices, known as "stand-by" mode, by which the device has a percentage of electric energy to keep a receptor functioning, and allows it to be turned on at the order of the control.

The characteristics of households and the contemporary way of life, highly depending on electronic household devices, consolidated the set of phantom loads associated to each of the electric devices as a not negligible element on the monthly energetic budget. It is stated, according to studies carried out in the year 2000 in the main Australian cities *(Energy Efficient Strategies, 2006),* that the monthly average consumption by concept of phantom loads in Australian households was 86.8Wh per person, a figure that grew over a period of five years, reaching 10.7% of the monthly energetic consumption, that is to say, 92.2Wh per person, of a monthly average household total consumption of 265kWh.

The Colombian context, and specifically regarding the city of Medellin, Antioquia, still has no record of studies or measurements carried out with the goal of quantifying phantom loads and the calculations for its incidence within the monthly total electricity comsumption in residential buildings, for which this investigation applied to a specific context is considered pertinent.

THEORETICAL FRAMEWORK

The term "vampire Load" refers to the existing similitude between the fangs of the mythical character and the two common terminals in an outlet. There is no clarity as to whom and when this concept was first used to define power loss in household appliances during "stand-by" mode; however, it is attributed to swiss engineer Sandberg, E. (1993) the first use of the term *"Leaking Electricity"*, during the conference *"Electronic home equipment – Leaking electricity",* in Rungstedlund, Denmark, according to which an electricity leak is defined as: *"Energy demand of television sets, CD players and other electronic devises during inactive mode"*, making this a first approach to the concept of phantom load.

Nowadays, definition of the phantom load concept is directly related with modes in the use of electrical household appliances: off, in passive waiting mode, active waiting mode, and programmed start. Power consumption is not considered phantom load during active mode: *"standby consumption (or phantom) is the one generated while the household appliance is not performing its primary function". (Energy Efficient Strategies, 2006)*

METHODOLOGY

For the investigation purposes, eleven study cases were done in residential buildings in the city of Medellín, with area, typology, and population number variations, considering only the socio-economic levels 4, 5 and 6. The decision to collect this information in high economic levels is based on the presumption that the amount of household electronic appliances is greater per capita, thus increasing the possibilities of phantom load loss. Next there is a general description of study cases:

Table 1. General Information of each Study Case

Study cases general information						
Case No.	Population	Socio-economic level	Household appliances	Most recent monthly electricity consumption data (kWh)	Monthly phantom load electricity consumption (kWh)	Phantom load (%)
SC01	4	4	35	592,00	36,05	6,90%
SC02	3	4	21	249,00	9,21	3,70%
SC03	4	4	23	264,50	10,36	3,92%
SC04	1	4	8	99,00	5,83	5,66%
SC05	3	5	11	105,00	4,22	4,02%
SC06	3	4	33	216,00	12,16	5,63%
SC07	2	4	10	107,50	1,16	1,08%
SC08	3	6	13	161,00	1,23	0,77%
SC09	2	5	17	146,00	1,38	0,95%
SC10	1	4	9	128,50	1,74	1,35%
SC11	1	5	4	91,00	6,41	7,04%

Number of household appliances	184
Total population	27
Monthly electrical consumption per person (kWh)	79,98
Monthly electrical consumption per house (kWh)	196,32
Monthly phantom consumption per person (kWh)	3,32
Monthly phantom consumption per house (kWh)	8,16

Each study case consists of the measurement of electricity consumption of all electronic devices that remain connected to an energy source, during time intervals of: 0, 5, 10 and 20 minutes, which allows to obtain a weighted average consumption, and decrease this way the possibility of calculating irregular and/or atypical power consumption levels. The result of this operation expressed in Wh, is then multiplied by the number of **daily hours of dispensability** of the household appliance; that is to say, how many hours in a day such appliance could remain disconnected without affecting the lifestyle of the inhabitants, and that for practical issues was defined as 7, which represents daylight or night hours destined to sleeping, obtaining this way data for "Phantom/Day consumption (Wh)". Finally, column "Phantom/month consumption (Wh)" is shown, which is equivalent to multiplying the latter column by 30, the number of average days in a month.

In a simultaneous way to the application of measurements, other data was collected through observation and surveys, related to the characterization of each electric household device, an a greater understanding population habits, as well as the effective state of electrical devices. Additional data collected: **a)** category of use; that is to say, what is the purpose of the household device: computing, refrigeration and/or heating, entertainment, cooking, accessories or laundry; **b) brand** of the appliance, c) a brief **description** in case it is relevant, and finally, **d) approximate age** in years according to categories: 0 – 5 years old, 5 – 10 years old, 10 – 15 years old, and older than 15.

Table 2. Information Collection Table

Room	Household appliance	Category	Approximate age	Stand-by mode consumption (Wh)					Dispensability hours / Day	Phantom load / Day (Wh)	Phantom load / Month (Wh)
				Min 00	Min 5	Min 10	Min 20	Average			
Store	Telephone	Accesorio	1 - 5	0,00	0,00	0,00	0,00	0,000	7	0,000	0,000
	Common fridge	Cocina	1 - 5	0,00	0,00	0,00	0,00	0,000	7	0,000	0,000
	Postobón S.A Fridge	Cocina	10 - 15	0,00	0,00	0,00	0,00	0,000	7	0,000	0,000
	Ultraviolet lamp	Accesorio	10 - 15	0,00	0,00	0,00	0,00	0,000	7	0,000	0,000
	Microwafe	Cocina	10 - 15	138,00	139,00	138,00	134,00	137,250	7	960,750	28.822,500
	Coffee maker	Cocina	5 - 10	0,00	0,00	0,00	0,00	0,000	7	0,000	0,000
Garage	TV	Entretenimiento	10 - 15	0,30	0,30	0,30	0,30	0,300	7	2,100	63,000

For every residential complex, a survey was performed regarding people's habits, concerning topics related to electric savings that represent a percentage of incidence in the total phantom loads, such as finding out if people disconnect or not cell phones and personal computers when these devices are totally charged, and their willingness or not to modify their conduct once informed with respect to this issue.

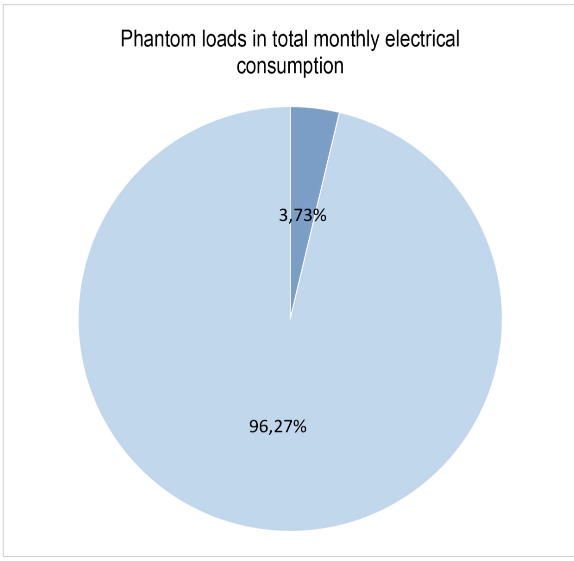
All measurements were done on a 20 minute time span for each device, through the use of a wattmeter called *Kill a Watt* with a precision range of 0.2%. Neither temperature nor humidity variations were considered at the moment of measurements, neither possible electrical fluctuations derived from the hour at which the electrical consumption was registered.

RESULTS ANALYSIS

- For the eleven study cases, **energy waste levels by way of phantom loads** are equivalent to **3.73%** of the total of monthly electric consumption for every household, which allows us to corroborate the existence of phantom loads in the urban residential sector in the city of Medellin. Next, the calculation of percentage representativeness of phantom loads in the monthly electric consumption, organized by study case and expressed in percentage:

Table 3. Calculation of Percentage Representativeness of Phantom Loads in the Total Monthly Electricity Consumption

Calculation of percentage representativeness of phantom loads in the total monthly electricity consumption		
Case No.	Phantom load (%)	Phantom loads average consumption (%)
SC01	6,90%	3,73%
SC02	3,70%	
SC03	3,92%	
SC04	5,66%	
SC05	4,02%	
SC06	5,63%	
SC07	1,08%	
SC08	0,77%	
SC09	0,95%	
SC10	1,35%	
SC11	7,04%	



Of all the study cases, SC08 showed the least percentage of incidences due to phantom loads, with a **0.77%,** and the SC11 the greatest, with a **7.04%.** The aforementioned are distant data from the average, because the majority of cases can be placed between **3** and **6%.**

- The analysis of **power consumption according to activity** shows that the greatest energy deviation is found in household appliances destined to Entertainment, with a **40.89%** of the total of electricity consumption by way of phantom loads, far from the second place taken by appliances related to Computation, with a **23.59%.** The activity that represented the least power expenditure due to phantom loads was Refrigeration/heating, with **0.43%,** due mainly to conditions of humidity and temperature in Medellin being close to thermal comfort range, reason for which these household electronic appliances are not commonly found for residential use.

Table 4. Calculation of Phantom Consumption According to Activity Type Related to Household Appliance

Calculation of phantom loads according to the type of activity related to appliance												
Usage categories	Percentage equivalent											Weighted average (%)
	SC01	SC02	SC03	SC04	SC05	SC06	SC07	SC08	SC09	SC10	SC11	
Accessory	6,64%	6,13%	27,76%	0,00%	0,00%	17,17%	0,00%	27,23%	60,52%	32,06%	6,56%	16,73%
Refrigeration/heating	0,89%	0,00%	0,00%	0,00%	0,00%	0,00%	0,00%	0,00%	3,88%	0,00%	0,00%	0,43%
Computation	7,70%	4,74%	24,57%	21,80%	10,69%	6,44%	0,00%	27,23%	20,71%	58,78%	76,80%	23,59%
Entertainment	4,82%	86,34%	41,80%	60,81%	85,07%	72,51%	12,22%	45,53%	14,89%	9,16%	16,64%	40,89%
Laundry	0,00%	0,00%	2,45%	6,58%	0,00%	0,00%	22,62%	0,00%	0,00%	0,00%	0,00%	2,88%
Kitchen	79,95%	2,79%	3,43%	10,81%	4,24%	3,87%	65,16%	0,00%	0,00%	0,00%	0,00%	15,48%

- Analysis of **electricity consumption according to age of household appliances** allowed investigating about the relevance of the "technological life" variable; in other words, incidence of age and the degree of technological update on energetic waste loads. Next, a graph that relates age to phantom consumption of household appliances:

Table 5. Age of household appliances and average consumption according to age

Appliances age and average consumption according to age												
Age of appliance (in years)	Average electricity consumption (Wh)											Weighted average (Wh)
	SC01	SC02	SC03	SC04	SC05	SC06	SC07	SC08	SC09	SC10	SC11	
1 - 5	1,26	3,48	2,28	3,70	0,00	1,87	0,21	0,30	0,52	1,25	12,71	2,51
5 - 10	0,79	0,72	1,24	2,76	3,28	1,10	1,07	0,63	0,67	1,10	0,00	1,21
10 - 15	23,04	0,00	5,55	0,00	1,18	3,82	0,00	0,73	0,09	0,00	2,54	3,36
>15	1,50	0,00	0,00	0,00	2,88	0,70	0,00	0,00	0,00	0,00	0,00	0,46

The average consumption in Wh of household appliances according to approximate age indicates that those that are between 10-15 years old have an average phantom consumption equivalent to 3.36Wh, the highest among analyzed appliances; however, consumption of those that are over 15 years old is only 0.46Wh; that is to say that, according to general performance, it is possible to state that there is no direct relationship between age and phantom load consumption, which allows to say that technological update of household appliances does not necessarily imply a decrease in phantom loads

- Another analysis item in this investigation seeks to establish what percentage of household appliances have electricity leakage in their secondary functioning modes, and simultaneously establish levels according to leak energy quantity. Established ranges for this analysis were: equal to 0Wh, less than 1Wh, between 1-5Wh, and more than 5Wh.

Table 6. Classification of Phantom Loads According Electrical Consumption

Classification of phantom loads according to electricity consumption												
Electricity consumption (Wh)	Equivalent percentage (%)											Weighted average (%)
	SC01	SC02	SC03	SC04	SC05	SC06	SC07	SC08	SC09	SC10	SC11	
Equal to 0	45,71%	28,57%	17,39%	12,50%	18,18%	42,42%	70,00%	38,46%	41,18%	33,33%	25,00%	33,89%
Less than 1W	22,86%	23,81%	21,74%	0,00%	9,09%	12,12%	10,00%	46,15%	41,18%	33,33%	0,00%	20,03%
Between 1 - 5W	22,86%	28,57%	43,48%	62,50%	45,45%	30,30%	20,00%	15,38%	17,65%	22,22%	25,00%	30,31%
More than 5W	8,57%	19,05%	17,39%	25,00%	27,27%	15,15%	0,00%	0,00%	0,00%	11,11%	50,00%	15,78%

Results according to the eleven study cases indicate that 33.89% of diagnosed household appliances did not have phantom loads, namely, electric consumption during secondary use mode is equal to 0Wh. Next, the graph summarizing classification previously mentioned:

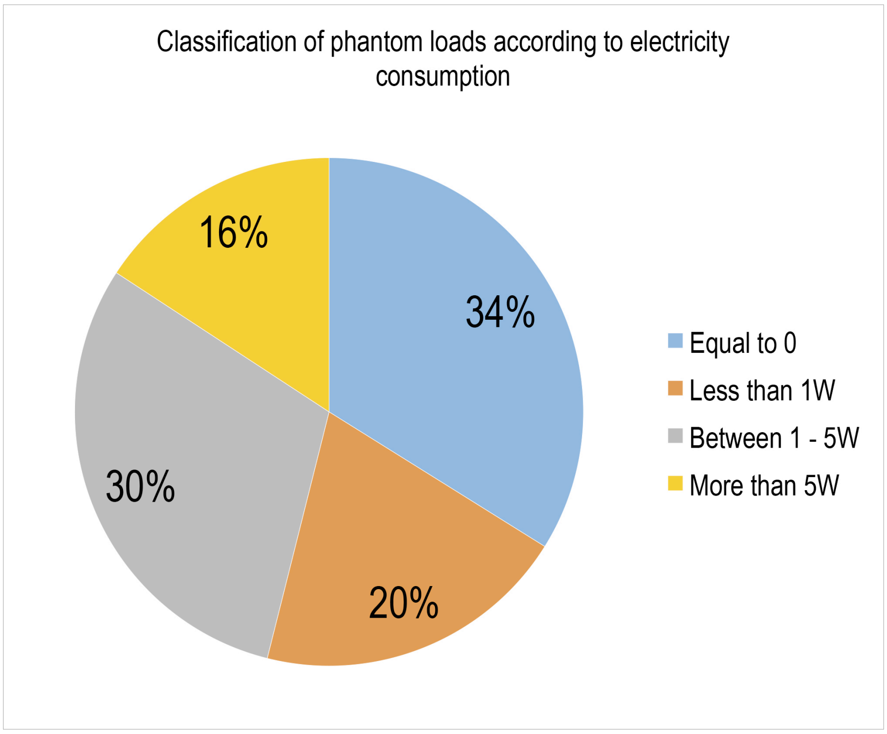


Figure 1. Classification of phantom loads according to electricity consumption

- According to statistics of the Mayor's Office of Medellín, in 2010 there were a total of 641,780 residential units in the city of Medellín. Extrapolating results from this investigation from the phantom loads data per household unit equivalent to 8.16kWh, means affirming that for the city's total households, the monthly electricity leakage is equivalent to **5,236,924.8kWh.**

Table 7. Number of households per Socio-Economic Stratum and Commune

Number of households per socio-economic stratum and commune								
No.	Commune	Socio-economic stratum						Total commune
		1	2	3	4	5	6	
1	Popular	13.106	22.870	16	0	0	0	35.992
2	Santa Cruz	4.022	25.419	8	0	0	0	29.449
3	Manrique	11.356	27.284	7.065	0	0	0	45.705
4	Aranjuez	4.043	14.223	22.532	15	0	0	40.813
5	Castilla	364	5.145	29.853	542	0	0	35.904
6	Doce de Octubre	7.042	27.464	12.435	0	0	0	46.941
7	Robledo	5.010	23.659	13.846	4.189	405	3	47.112
8	Villa Hermosa	14.809	17.079	10.634	887	0	0	43.409
9	Buenos Aires	1.474	11.030	26.444	3.956	491	286	43.681
10	La Candelaria	1	2.136	9.378	14.565	894	1	26.975
11	Laureles Estadio	0	63	353	13.676	25.250	0	39.342
12	La América	0	635	9.307	13.253	7.701	0	30.896
13	San Javier	17.010	18.643	10.289	2.469	0	0	48.411
14	El Poblado	16	687	611	1.546	7.638	30.058	40.556
15	Guayabal	100	3.415	11.283	5.268	0	0	20.066
16	Belén	1.210	11.521	23.978	15.742	14.076	1	66.528
Total x stratum		79.563	211.273	188.032	76.108	56.455	30.349	
Household per stratum (%)		12,40	32,92	29,30	11,86	8,80	4,73	
Total household		641.780						

The cost of that wasted energy is COP $ 2,038,858,872 million pesos monthly, according to the cost of 1 kWh as of January 2014. Data, discriminated by stratum, is shown next:

Table 8. Cost of Wasted Energy due to Phantom Loads According to Stratum

Cost of wasted energy due to phantom loads according to stratum				
Socio-economic stratum	Number of households	Monthly phantom consumption (kWh)	Cost kWh	Cost phantom loads consumption COP $
Stratum 1	79.563	8,16	379,07	$246.105.163
Stratum 2	211.273	8,16	379,07	$653.512.010
Stratum 3	188.032	8,16	379,07	$581.622.688
Stratum 4	76.108	8,16	379,07	$235.418.118
Stratum 5	56.455	8,16	454,88	$209.550.843
Stratum 6	30.349	8,16	454,88	$112.650.049
			Total	$2.038.858.872

- Based on results of the survey made to one person per household about some habits and their influence on phantom loads, results indicate that 63% of those interviewed decide not to disconnect their laptops from electricity once they are completely charged, and 90% decide not to disconnect their desktops when they finish using them. However, the survey indicates that 55% of those interviewed in fact disconnect their household electrical appliances at night, or during their absence during the day.

Table 9. Results survey made to a resident per residential unit

Results survey made to a resident per residential unit													
Questions	Casos de estudio											Yes	No
	SC01	SC02	SC03	SC04	SC05	SC06	SC07	SC08	SC09	SC10	SC11		
Do you disconnect your laptop charger once the device has been fully charged?	No	No	No	Sí	Sí	No	No	Sí	Sí	No	No	4 36,36%	7 63,64%
Do you disconnect your desktop once you're donde using it?	No	No	No	No	Sí	No	No	No	No	No	No	1 9,09%	10 90,91%
Do you disconnect your household appliances during the night or when you are absent during the day?	Sí	Sí	Sí	Sí	No	No	No	Sí	No	No	No	5 45,45%	6 54,55%
Assuming that important household appliances such as the fridge, surveillance and security systems, and at least one telephone were to remain turned on and functioning, would you be wiling to disconnect all your household appliances if there was an automatic mechanism that did it for you?	Sí	Sí	Sí	Sí	Sí	Sí	Sí	Sí	Sí	Sí	Sí	11 100,00%	0 0,00%

The results of the survey show that, even though there is a degree of ignorance about the levels of electrical consumption during secondary functioning modes in some devices, and that the majority of the people do not disconnect electrical devices when done using them due to laziness or lack of knowledge, there is a high degree of acceptance to the proposal of solution alternatives that take care of disconnecting electronic appliances automatically, as is proposed in the last question of the survey, to which 100% of those surveyed answered in an affirmative way.

CONCLUSIONS

According to set objectives for the development of this investigation, this has been achieved:

- Demonstrating the existence of phantom loads in the urban residential sector of the city of Medellín, Colombia, according to analysis of electricity consumption made in eleven residential units with stratum 4, 5 and 6.

- Quantifying percentage incidence of phantom loads cunsumption over the total electricity consumption of diagnosed households, equivalent to **3.73%** of the monthly electricity consumption; that is to say, an average of **8.16kWh** per house.

- Establishing independence between phantom loads and technological update expressed in age and technological updating of appliances, through quantitative demonstration that there is no relationship between both variables.

- Quantifying economic and energy investment at a city level (Medellín) that represents loss of electricity by way of phantom loads in residential units, equivalent to **5,236,924.8kWh** and **COP $2,038,858,872** million pesos.

ACKNOWLEDGMENTS

The development of this investigation was possible thanks to the participation of Architecture students of Universidad Pontificia Bolivariana, Juan Camilo Paniagua, Mateo Alzate, Juan Camilo Fernández and Valerie López, who were active members in collecting information of every study case. Also thanks to the people who allowed student access to all rooms in their households with the goal of making all pertinent measurements.

Renewable Energy Application in Floating Architecture

Changho Moon, PhD
[Kunsan National University]
mchangho@kunsan.ac.kr

ABSTRACT

Climate change like global warming brings sea and river level rise. Usable land in urban area becomes less and the price of real estate increases due to continuous development. Reclamation method for land supply has been regarded as environmentally negative. And people want to enjoy the life on water rather than on land or mountain according the improved income level. Therefore floating architecture on water has been emerging as a creative and alternative to the building on the land of waterside region. The aim of this study is to investigate the status of renewable energy applications in sample floating architectures and to suggest some reference ideas for new building projects around the waterside. Most popular renewable energy sources for the floating architecture are solar heat energy, solar photovoltaic energy and hydrothermal energy. Especially hydrothermal use of the water underneath the floating building may have a huge advantage in tropical region and cold region because there is a great temperature difference between the water and the outdoor air in extreme climate regions. Therefore hydrothermal energy can be used for air-conditioning in tropical region and heating in the cold region. Wind energy also can enhance the possibility of self-supporting floating architecture if building intergrated samall wind turbine with little noise is developed. Hybrid system of solar photovoltaic energy with wind power will be highly popular when the design of the hybrid system is intergrated with that of floating architecture. Of course, detailed disadvantages of floating architectures should be investigated and countermeasures to overcome are to be suggested for further study.

INTRODUCTION

Climate change like global warming atmosphere brings a rise in sea and river level. Usable land in urban area will be less and the price of real estate is going to rise due to continuous expanding development. Reclamation method for new land supply is regarded as environmentally negative and very difficult to proceed without the public consensus. People like to live and enjoy leisure activities near or on water according to the improved income level. New floating buildings such as house, restaurant, school, exhibition and meeting, yacht club house, hotel, ferry terminal, prison, and café are being built around the world. Therefore floating architecture on water has been emerging as a feasible and strong alternative.

Floating building is easy to get various renewable energy sources because there are not so many physical obstacles in the sea or river. More solar and wind energies can be obtained on the water than on the urban land. Especially hydrothermal use of sea or river water beneath the floating building might be a great advantage because the temperature of water is usually lower than that of outdoor air in summer and the reverse in winter. Therefore hydrothermal energy can be used as cooling in tropical region and heating in the cold region.

Floating Building can be generally regarded as positive in ecosystem because the building has a closed premises services system, sometimes stimulates diversity in water milieus and provides a protected habitats for small fish and other aquatic animals. The underside of floating building foundation can even be rough to encourage the attachment and growth of water plants, algae and shellfish. The water plants have a purifying effect on the water (Koen Olthuis & David Keuning, 2010). A large-scale floating architecture or a number of floating buildings can be criticised as throwing a shadow to the bottom of the water, so some countermeasure for the passage to give the sunlight to the bottom of the water should be considered.

The aim of this study is to review the concept of floating architecture and renewable energy in architecture, to investigate the renewable energy applications in planned and realized floating architectures, and to suggest some reference ideas for new building projects around waterside. Research method includes the navigation of related websites, site-visits, and the review of reference documents and literatures. Sample floating architectures with strong points of renewable energy applications are chosen to analyze.

FLOATING ARCHITECTURE

As the advantageous points of floating homes have been known to public, the new residents with interesting have rebuilt the new and luxurious floating homes replacing the old and poor ones in San Francisco and Seattle, USA. In Portland, USA, a large number of modern and large loating homes have been built on the Willamette River and near net zero energy floating home with solar PV system, solar water heating, hydronic heating, rainwater collection and reuse, and reclaimed and certified wood has been built in the North Portland's Tomahawk Island Floating Home Community. In Steigereiland IJburg, Amsterdam, Netherlands, there are 75 floating homes consisting of detached and row houses. So floating architecture becomes popular and familiar with the ordinary person.

Figure 1 Floating Homes in Seattle, USA(left) and Portland, USA(right)
(Source: photos by the author, 2012)

Floating architecture can be defined as a building for living or working space that floats on the water with floatation system, is moored in a permanent location, does not include a water craft designed or intended for navigation, and has a premises services (electricity, water/sewage, gas) system served through connection by permanant supply/return system between floating building and a service station on land, or has self-supporting service facilities for itself.

RENEWABLE ENERGY IN ARCHITECTURE

Renewable energy is generally defined as energy that comes from resources which are naturally replenished on a human timescale such as sunlight, wind, rain, tides, waves and geothermal heat. Renewable energy replaces conventional fuels in four distinct areas: electricity generation, hot water or space heating, motor fuels, and rural (off-grid) energy services (Renewable energy, Wikipedia, 2014).

In architecture, wind power, solar energy and geothermal energy in renewable technologies are generally being applied in the design and practice. Especially various applications of solar energy through solar heat panel and solar photovoltaic (PV) cells, and hydrothermal energy like geothermal energy are usually introduced in floating architectures on water.

Wind power, tidal power and wave power can be considerable if there is proper system to be intergrated with floating architecture and to be harmonized with the natural environment. Wind power is highly expected to be used in floating architecture because wind power resource is abundant on water space and small wind power turbine for the building is under development.

Hybrid system of solar energy with wind power will be useful and complementary because the sun usually shines when there is no wind in day time and the wind usually rises when there is no sun. So solar - wind hybrid renewable energy system will be popular when the design of the hybrid system can be intergrated with that of floating architecture.

PLANNED FLOATING ARCHITECTURE

Floating Mosque, Dubai (2007)

The floating mosque has modern and traditional Islamic designs. The interior is characterized by giant funnel-shaped transparant columns that do not only support the roof, but also allow filtered light to illuminate the inner space (Waterstudio, 2014). The building has 1 storey superstructure and the large pontoon made of concrete and styro-foam, and basically connects the water supply/return lines from the station of inland. But the building is designed self-supporting as possible in terms of energy.

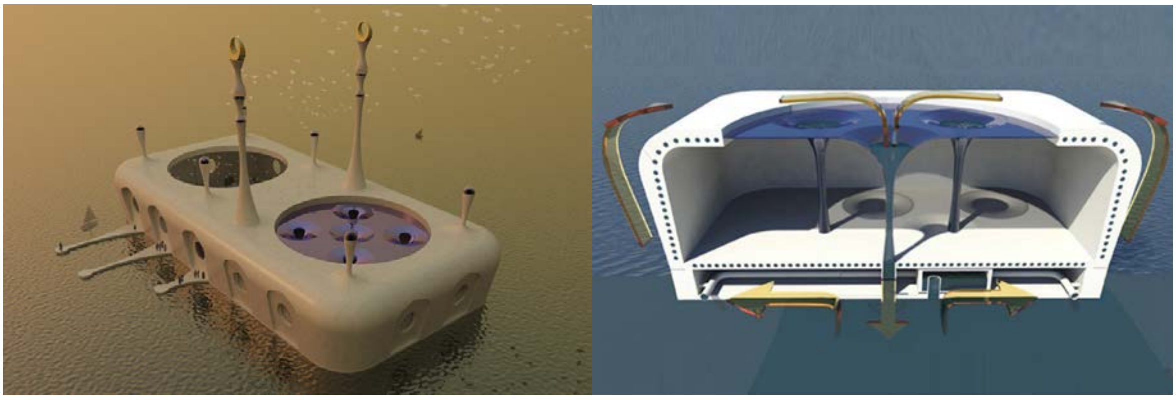

Figure 2 Model of Floating Mosque (left) and Water Cooling System (right)
(Source: http://www.waterstudio.nl/ projects/30, 2014)

The flat-roofed floating mosque is environmentally friendly by using the hydrothermal temperature, pumping sea water from the Arabian Gulf through a vein-like system of wall and floor cools the building structure down by 15 degree Celsius(from 45 degree to 30 degree), reducing the cost of cooling by around 40 percentage. Air conditioning by the electricity from solar photovoltaic cells brings the temperature down even further to 21 degree Celsius. Electricity from solar energy is also required for the pumping machine (James Reinl, 2007).

The roof and walls absorb little heat because of porous external cladding, consisting of a sponge-like ceramic material with extremely low density. The thick external walls have a high accumulative capacity due to their high density and large size (Koen Olthuis & David Keuning, 2010). Therefore, water cooling system can be more effective than any other measure.

The Ark (2010)

A massive dome-shaped building concept with living space of around 14,000 square meters, the Ark, is proposed to get maintenance of security and precaution against extreme environmental conditions and climate change together with protection of natural environment from human activities. The arch-shaped building has a structure that enables it to float safely and stay autonomously on the surface of the water. The Ark was also designed to be a bioclimatic building with independent life-supporting systems, including elements ensuring a closed-functioning cycle (Alison Furuto, 2011).

The Ark concept, designed with the UIArchitects Work Program “Architecture for Disaster Relief,” could be realized in various climates and especially in seismically dangerous regions because its basement is a shell structure without any ledges or angles. A load-bearing system of arches and cables allows weight redistribution along the entire corpus in case of an earthquake. And also its prefabricated frame can allow for fast construction (Anastasia Vdovenko, 2014).

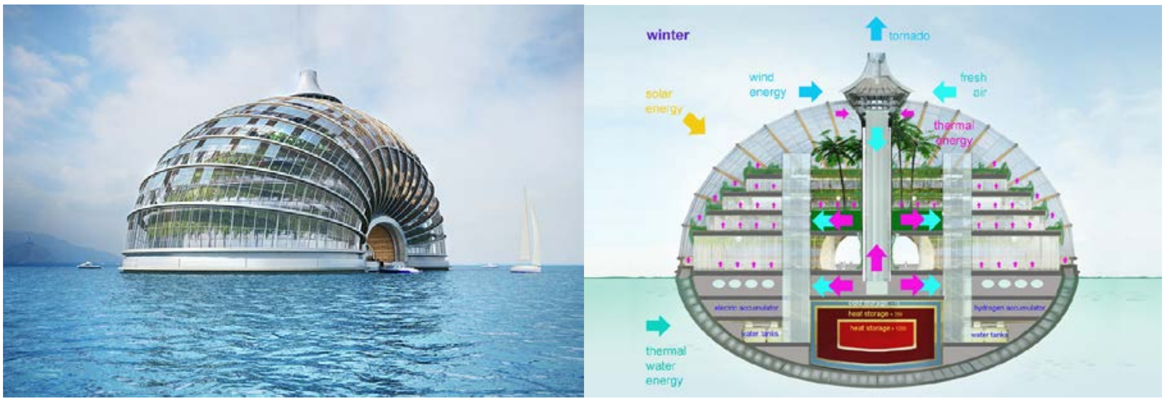

Figure 3 Perspective (left) and Section Diagram (right) of The Ark
(Source: http://remistudio.ru/en/pages/52.htm. 2014)

The building has an optimal relationship between its volume and its outer surface, significantly saving materials and providing energy efficiency. Its shape is convenient for installing solar photovoltaic cells at an optimal angle toward the sun and wind turbine on the roof.

The cupola, in the upper part, collects warm air which is gathered in seasonal heat accumulator to provide an uninterrupted energy supply for the whole building complex independently from outer climate conditions in winter. The heat energy from the surrounding environment - the outer air, water or ground - is also used.

The structural solidity is provided by compression of timber arches and tension of steel cables. The framework is covered by a special foil made of EthylTetraFluoroEthylene(ETFE). It is a strong, highly transparent foil that is self-cleaning, recyclable, and more durable, cost-efficient and lighter than glass. The foil itself is affixed to the framework by special metal profiles, which serve as solar energy collectors for heating water and as gutters for collecting rainwater from the roof (ARK, 2014).

REALIZED FLOATING ARCHITECTURE

IBA Dock, Germany (2009)

In 2010, the international building exhibition IBA had a slogan “City in a Climate Change” with a goal of a CO_2-neutral city development. The IBA Dock as the information and event center of Hamburg is constructed upon a floating pontoon. The building is now being used for Urban and Architecture information center in Hamburg and also the 2013 Hamburg International Gardening Exhibition. The IBA Dock not only houses the exhibition IBA, but is also itself an exhibition of innovative building and integrates numerous renewable energy technologies (IBA DOCK, 2014).

The IBA Dock has 3 storeys and 1,640 square meters floor area. The building is situated on an approximately 43m long and 26m wide concrete substructure pontoon and the superstructures of building are made of steel in prefabricated modular construction (IBA Dock/Architech, 2012). The building is setting new standards in the area of climate protection. In addition to 25cm thick insulated outer walls, the IBA Dock uses the sun and water of the Elbe for generating energy.

The building is based on “zero balance concept”, which focuses on solar energy management and systems that provide buildings with sustainable heat and cooling all year round. 16 rooftop solar heat panels with a total surface area of about 34 square meters are positioned facing south at the relatively steep angle of 50 degrees to maximize the heating of water in the colder months.

Solar energy captured from these collectors feeds into an electric heat pump that draws its environmental heat from water taken directly from the Elbe using a heat exchanger built into the base of the concrete pontoon. This provides both the heating and cooling requirements for the water and air conditioning of the building, with excess energy able to be temporarily saved for later use. The building features heating and cooling ceilings that either heat the rooms in colder months or cool the room in warmer months.

Figure 4 Exterior (left) and Interior (right) of IBA Dock
(Source: left photo by the author, 2011, right photo from
http://www.archdaily.com/288198/iba-dock-architech/, 2014)

The 44 kW heat pumps, along with a ventilating machine that provides air exchange for the entire building, are powered by 103 square meters of south-facing solar photovoltaic cells located on the roof terrace and angled at 30 degrees that deliver 14.8 kWp (kilowatt peak). The electricity needed by the heat pump is covered by the photovoltaic device on the IBA Dock. No further cooling or heating energy is needed (Darren Quick, 2012).

Floating hotel "Salt & Sill", Sweden (2008)

The first floating hotel in Sweden opened alongside the famous seafood restaurant "Salt & Sill". The location is small but peaceful island and very limited space was available around the restaurant. Therfore a floating hotel was the only way to realize the owners' dream to offer a complete service with food, drink, conference and accommodation at the same time (SALT & SILL, 2014). The hotel is very popular even though it is located in rural and coastal area in Sweden. So there are many visitors with different purposes all the year over.

Figure 5 Exterior (left) and Roof (right) of Floating Hotel "Salt & Sill"
(Source: photos by the author, 2011)

The floating hotel has 2 storeys and 23 rooms with 46 beds. All the rooms have their own entrance and access to an outdoor seating area. The building is mainly made of wood on concrete pontoon. Premises services (electricity, water supply and sewage) are served through connection lines between the floating hotel and the service station of near land.

During the construction of the building, protection of environment has been the most important agenda. A positive impact on outdoor life, little or no effect on the island environment, no noise and pollution of air should be kept. The building used local raw materials such as the pine wood from Swedish forests, and only environmentally friendly paint. They have even used the left over quarrying stone to build a new lobster reef under the concrete pontoon for the consideration of environment. In the hotel, heating energy is actually generated from the warm sea water underneath the floating building in winter (Costas Voyatzis, 2008).

Autark Home, Netherlands (2012)

Autark Home is a self-sufficient and passive floating home with European passive house certificate. A prototype of Autark Home is currently anchored in the river Maas, Maastricht, Netherlands and draws a huge number of eco-concious visitors due to its unconventional construction design.

The floating home has 2 storeys and 109.4 square meters floor area, outer wall with 55cm thick massive EPS, isolated windows and doors, triple glass and no cold bridges. In terms of energy, there is an ioloated water tank with capacity of 4,000 liters and 6 solar heat panels on the roof to keep the water at a temperature of 70 to 80 degree Celsius for 4 to 5 days (Autark Home, 2014).

Figure 6 Exterior (left) and Interior (right) of Autark Home
(Source: http://www.autarkhome.de/, 2014)

River water is converted to gray water and high-quality drinking water through a filter. And drinking water is made again by purification system through reverse osmosis in combination with the sand and UV filter. Gray water can be used as flushing & washing water and for the floor heating & cooling. Before the waste water returns to the river, the water is cleaned for 90% by a built-in filtration system. Like other passive houses, each room has its own ventilation. The incoming fresh air is heated or cooled by outgoing exhausted air through a heat recovery ventilation system.

The electricity is supplied by 24 solar photovoltaic cells with a total output of 6,360 Wp(watt peak). The electrical energy is stored in 24 batteries, each with a capacity of 1000 Ah, supplying enough electricity for 4 days for a normal family. The system can deliver 5300 kWh a year. On the display of the monitoring system in the living room, solar production can be viewed. In adverse weather conditions, a bio-diesel generator supplies the home with additional power (REM, 2012).

Even though there are no service utilities to be connected around the floating building, this kind of floating building with self-sufficient system can be built and operated without any problem. So floating architecture with self-sufficient system such as water treatment and electiricity power system can be built freely any distance away from the quayside.

RENEWABLE ENERGY APPLICATIONS IN SAMPLE FLOATING ARCHITECTURES

Renewable energy applications in sample floating architectures are as follows (see Table 1);

Table 1. Renewable Energy Application in Samples

Name of building	Renewable energy source	Remark
Floating Mosque	hydrothermal energy, solar PV cell	structure cooling system by water
The Ark	solar PV cell, solar heat panel , wind power	bioclimatic building, ETFE
IBA Dock	hydrothermal energy, solar heat panel, solar PV cell	prefabricated modular construction, heat exchanger
Floating hotel "Salt & Sill"	hydrothermal energy	environment protection
Autark Home	solar heat panel, solar PV cell	self-sufficient & passive system, bio-diesel generator, heat recovery ventilation system

Most popular renewable energy sources for the floating architectures are use of sloar energy (heat panel and PV cell) and hydrothermal energy. Especially use of hydrothermal energy may have a huge advantage in tropical region and polar region because there is a great temperature difference in the water and the outdoor air of the extreme climate regions.

Use of hydrothermal energy in renewable energy is applied to the projects such as Floating Mosque, IBA Dock, and floating hotel “Salt & Sill”. And solar PV cells are mostly used in the projects like Floating Mosque, The Ark, IBA Dock, and Autark Home. Solar heat panels are used for The Ark, IBA Dock and Autark Home.

Until now, it is very hard to find out wind power application in floating archietcture. Usually there is more wind resource on water space of sea or river than on urban land because there is daily land and sea breeze circulation and no windbreak on water. If small wind turbine with little noise is developed, it will be applied more often for the floating architecture on water than for the building on urban land.

Usually hybrid system of solar energy with wind power will be useful and complementary because the sun shines when there is no wind in day time and the wind usually rises when there is no sun. So solar - wind hybrid renewable energy system will be more popular when the design of the hybrid system is intergrated and harmonized with that of floating architecture.

CONCLUSION

Due to the climate change, people’s preference to live and enjoy activities on water, and frequent natural disasters like flooding & earthquake, floating architecture can be a strong and attractive alternative to the existing building on land. This paper aimed to investigate the renewable energy applications in floating architecture and to suggest some reference ideas for new building projects around waterside. Sample floating architectures with strong points of renewable energy application are chosen to analyze.

Comparing with the usual buildings on land, floating buildings on water have great advantages in terms of using renewable energy. Possibilities of solar energy and wind power are much higher in floating architecture because there are no obstacles around water space. And hydrothermal use of the water beneath the floating architecture is easier and more economic than geothermal use in the building on land.

Most popular renewable energy sources for the floating architecture are use of solar energy and hydrothermal energy. Especially use of hydrothermal energy may have a huge advantage in tropical region and polar region because there is a great temperature difference in the water and the outdoor air of the extreme climate regions.

It is very hard to find out the wind power applications in realized floating archietctures until nowadays. Usually there is more wind resources on water than on urban land because there is no windbreak on water space. And also there is daily land and sea breeze circulation around watersides. If small wind turbine with little noise is developed and integrated with the floating building design, wind power can have the priority to be applied due to product efficiency.

Hybrid renewable energy system of solar energy with wind power will be more popular when the design of the hybrid system is intergrated and harmonized with that of floating architecture. And also tidal power and wave power can be considerable to apply if proper system for the floating building is developed.

By the way, disadvantages of floating architectures such as shadows to the bottom, water pollution from concrete pontoon, and other negative effects to the ecosystem should be investigated in detail and countermeasures to overcome are to be suggested for further study.

ABSTRACT

The Luminescent Solar Concentrators (LSC) are transparent plates which contain dispersed fluorescent dyes that absorb a part of the solar light and emit it into the inside of the plate. By means of the total internal reflection, the emitted radiation is led towards the thin edges of the plate where it is concentrated on small surfaced conventional solar cells. The LSC seems a promising technology with large diffusion potentialities in architecture thanks to the transparency combined with energy production. In fact LSC technology could be positively integrated in transparent components (e.g.. shading devices, bow windows, greenhouses, glazed courtyards). The first experimental application of LSC technology at real scale is a bicycles shelter in Rome. The architectural and structural project has been designed in order to assess the LSC components performance in three different orientations (tilted east and west facing and a vertical west facing) and in combination with a shading system which improves the PV production.

INTRODUCTION

The LSC are transparent plates (plastic or glass) which contain dispersed fluorescent dyes that absorb a part of the solar light and emit it into the inside of the plate. By means of the total internal reflection, the emitted radiation is led towards the thin edges of the plate where it is concentrated on small surfaced conventional solar cells. This technology enables designers with a new tool to generate electricity while providing natural light inside the building thanks to its transparency. The LSC technology offers significant potential advantages over conventional silicon panels and solar concentrators based on mirrors or lenses. The plates can in fact collect both the direct and diffuse solar radiation, being efficient even under cloudy skies, and their installation is not subject to orientation problems. LSC plates are also made of cheap materials and significantly reduce the silicon surface needed to generate the same energy power. Even if the performance of LSC technology is not comparable to that of traditional photovoltaic, its complete transparency allows to make all glass surfaces energy producers. In particular this aspect is related to the desire of lightness and visual permeability of contemporary architecture. In addition, the presence of colour allows to characterize the building envelope.

The research carried out by Polytechnic University of Milan for Eni S.p.A., has the objective to study the development of building components based on LSC technology. The research focuses on the possible diffusion and integration of LSC technology in the built environment, analyzing mainly two aspects: the production of electrical energy and the interior lighting conditions.

Authors A and B are professors in the Department of Architecture and Urban Studies, Politecnico di Milano, Italy
Author B is a researcher in the Department of Architecture and Urban Studies, Politecnico di Milano, Italy
Author C is a researcher in the Eni- Donegani Research Group, Novara, Italy

POTENTIAL DIFFUSION IN THE BUILT ENVIRONMENT

LSC panels can be used in a lot of different ways both in new buildings and in retrofit. On a morphological level the application of these components depends on their shape and their position relative to the building. The terms, purely evocative, that have been identified to indicate the different “scenarios of use” are: “between” (connection spaces between buildings, vertical connections, stairs and elevators, atria, light chimneys); “front” (curtain wall, fixed or opening windows, bow-window, double skin envelope, vertical or horizontal shading devices); “top” (volumes added as coverage as skylights, sheds, top of light chimneys, and technological spaces); “outdoor” (where LSC are used to build installations in open spaces such as urban equipment in parks and streets, temporary buildings, road barriers, etc.).

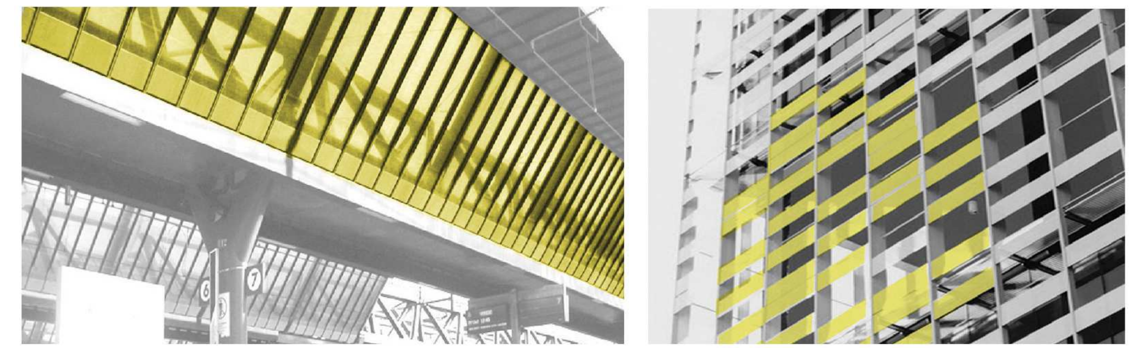

Figure 1 Examples of application of LSC in infrastructures and as shields on building facades (i.e. from left to right: A. Mangiarotti, studio 5+1AA, Jean Baptiste Pietri).

The colour of the LSC can be considered a problem but also a potential element to introduce colours pattern in the built environment and to modify the colour temperature in the interiors especially in offices where the dominant white finishing and artificial light with cold temperature require a warmer contribution. In fact, the application possibilities of LSC become even more interesting if measured at the sensorial level considering also the possible combinations with other materials: it is possible to emphasize the plate transparency or couple it with translucent materials to obtain a component that reduces visual permeability but lets the light pass through and therefore it is able to emphasize the value and charm of diffuse light. Different chromatic effects can be obtained: monochromatic ones using only panel of the same colour alternating with clear glass, or polychromatic ones combining the available colours of LSC (yellow, orange, red). Moreover modulating the size and the number of LSC panels and combining them with other materials (e.g. metal, glass, wood), different aesthetic effects can be achieved.

Also in this case the terms, purely evocative, that have been identified to indicate the different “sensorial scenarios” are: “transparency” (the plate is used as an element that guarantee the inside/outside visual contact and chromatically characterizes the architectural envelope); “translucency” (it is the scenario where LSC layers are coupled with a translucent element -e.g. satin glass- to have a component through which view is not possible but light can pass); “protection” (it regards the use of LSC elements as shading devices with the aim to modify the color quality of light and the perceptoin of colors in the room) and “opacity” (it is the scenario where LSC and an opaque layer are couped to increase the color intensity; this option does not permit the lighting, but increases energy efficiency).

Figure 2 Two possible visual effects of LSC: coloured transparency (G. Le Penhuel Architectes, Collège A. Schweitzer, Creteil, photo by J. Callejas), coloured translucency (DAPStudio E. Sacco-P. Danelli + architect P. Giaconia, Centro culturale Gritti, Ranica, photo by A. Bello).

THE EXPERIMENTAL APPLICATION

The first application at real scale of Eni technology was a shelter for electric bicycles in Rome. This project allowed to verify the strengths and the limitations of LSC panels from the energy production viewpoint (the shelter is still under monitoring) and from the construction process integration viewpoint (planning, design and implementation). The shelter is the ideal tool to simultaneously test the panels in different positions since the PV modules can be positioned with different orientations. Three orientations have been selected: inclined facing east, incline facing west and vertical east-west. The bike shelter was also equipped with a shading system made of reflective slabs plates placed at proper distance from the LSC to verify the PV production due to the increased indirect radiation on the LSC plates. The concept chosen for the project, called "energy module", defines the shelter as a set of modular free-standing elements that can be placed in different configurations in urban contexts.

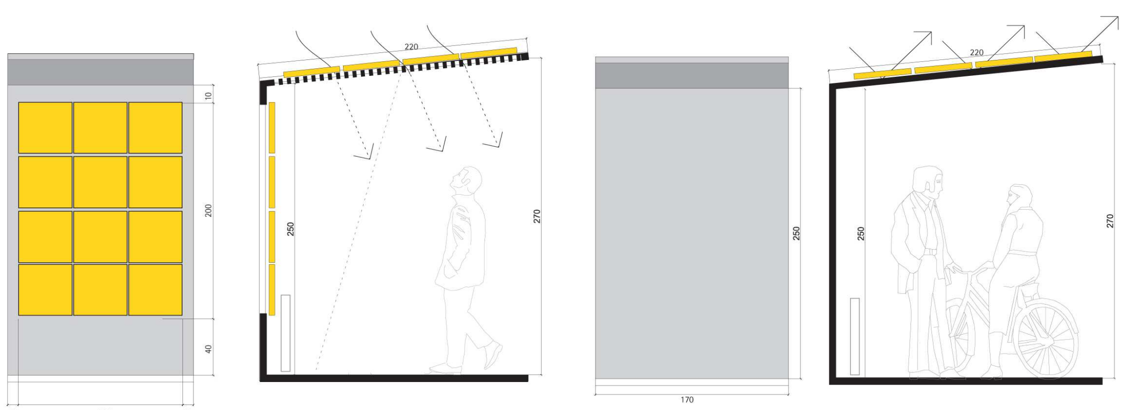

Figure 3 Two possible types of energy modules (from left to right): "shielded module" (with slats that filter light) and "full module" (with a reflective panel).

The modules can be combined, with more or less spacing between them, with different logics depending on the context in which they are placed. The frame module was developed in collaboration with Secco Sistemi S.p.A using only their standard products to minimize the process due to time constraints. The steel frame makes the module self-supporting and able to withstand the final assembly loads. The photovoltaic modules are made of 6 LSC panels each obtained with PMMA plates with dimensions of 50x50 cm assembled with properly dimensioned silicon solar cells connected in series/parallel. The panels are then connected in series to the stiffening structure made of painted steel, with dimensions of 108,4x161,8 cm. The panels are inserted into the frame and glued to ensure the resistance to atmospheric agents. Each module is equipped with 88 PV cells IXYS located on the 4 sides and connected in in parallel on each side; the four sides are connected in series and the panels that are connected in series using the structural steel elements in steel as ducts.

Figure 4 Twenty components made of 6 panels each have been used to build the shelter in Rome: 24 have been postioned on the roof and 8 in the vertical structure.

The selected steel profiles are glass retention systems bolted to steel box-shaped profiles for securing the LSC plates. A C-shaped aluminum frame is applied to the panel to protect the cells and bus. The profiles are equipped with butylic gaskets.

The peak power produced by every module is equal to14 Wp; the six modules are connected in series The electrical values evaluated in the flash test are listed in Table 1.

The average solar radiation per year on a horizontal unobstructed surface is expected to be 1307 kWh/m2 year. The average solar radiation per year on a unobstructed inclined surface (γ = 0°; ψ = 30°) is expected to be 1443 kWh/m^2 year. Average radiation on the module.

During the first monitoring period the module has been inclined 10° (γ = 0°; ψ = 10°). The average value on this surface is expected to be 1381 kWh/m^2 year. The average concentration factor for the panel has bees extimated between 8 and 20% with lower values in the late afternoon.

Table 1. Performance features of the experimental module LSC

Caracteristical data of the LSC module	Units	Value
Tension VMMP	V	24.29
Electricity IMMP	A	0.58
Electricity ISC	A	0.63
Power PMMP	W	14.1
tension VOC	V	30.16

Table 2. Recorded values for the LSC prototype during a three days monitoring in June

Day	Month	Daily Radiation [Wh]	Average Power [W]	Energy produced [Wh]
27	June	5557	10,87	79,74
28		6278	8,70	87,00
29		6617	8,59	85,88

Electrical scheme

The plant in question is stand-alone, with island operation. All the electrical loads need to be fed with alternating current at 230V, therefore the facility is equipped with an inverter able to supply the 230V to the loads drawing the necessary energy from the batteries. In detail, the generator of this photovoltaic system, made of photovoltaic modules and their connections and mechanical supports, is composed of a total of 32 prototype modules with monocrystalline silicon cells, installed at 3 different orientations and inclinations, as shown in the following summary table.

The different PV modules are connected in series of two modules each, thus forming a total of 16 strings. These strings are then grouped into three different sections, each of which is characterized by a uniform application type and is constituted by the electrical connection in parallel of the strings that compose it. The entire system is then equipped with a monitoring system able of measuring the voltage and current produced by each string, in addition to the main environmental data.

The electical needs for the bike shelter are related to: monitoring system for data collecting (solar radiation, temperature of the modules and air temperature, voltage and electricity); Personal computer with 19” touchscreen IP65 to visualize the energy produced and a multimedia description of the project; Back LED lighting of the Eni logo; Local LED lighting (positioned in the frame structure); N°3 electrical bikes.

System monitoring and remote control

The photovoltaic plant in question is equipped with an acquisition and monitoring system able to measure the following parameters: current strength of each string, the tension of each string, operating temperature of 3 photovoltaic modules, ambient temperature, radiation on the 3 different orientation planes under which the modules were mounted. The criteria selected for the analysis are: comparison between the integrated production of the LSC modules and the one estimated for traditional PV panels, definition and selection of significant days and tracking of the power supplied under different irradiation conditions, keeping the data coming from different panels orientations separate (bicycles side, motorcycle side, vertical wall), distinction of the strings according to the presence or absence of a back reflective panel, analysis of the historical production of the best performing strings.

The Eni photovoltaic shelter can nominally produce about 500 watts of electricity generated by 192 yellow transparent photovoltaic slabs, each of which is made of a plastic material with a minimum amount of dyes patented by Eni.

FUTURE DEVELOPMENTS

From the point of view of the type of component for the realization of the PV module, the initial choice fell on a frame with steel profiles with standard press-bents. The selected frame therefore guaranteed the same durability and mechanical strength of a traditional window frame with also the possibility to be easily opened for slabs repositioning. The next step is focused on a new fiberglass component structure which guarantees lightness, higher thermal and electrical insulation and minimum interference with the LSC energy performance in terms of minimum shading effect on solar cells.

Furthermore we are investigating the possibility of producing new components based on LSC technology. Nine concepts for different building components based on LSC technology have been defined. These components have been chosen for the potential diffusion in the built environment as well as for the possibility to be integrated in current building technologies. The dimentions of the LSC plates is based on a 50x50 cm module made in PMMA that can be aggregated to arrive at the desired dimensions. Each component will be studied and analyzed with reference to the current building regulations paying particular attention to the elements of the structural frame.

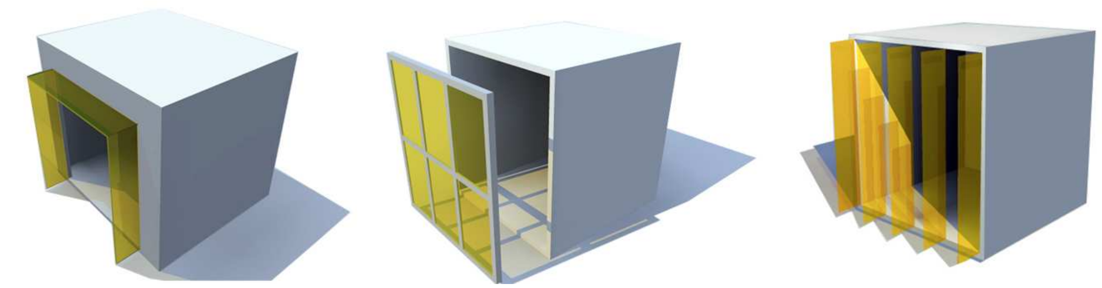

Figure 5 Some concept design for the future application developments.

CONCLUSION

The shelter, which is still in the monitoring phase, showed that the LSC are far less sensitive to the orientation than traditional photovoltaic panels; LSC are therefore able to exploit the diffused light and to work even in low lighting conditions (cloudy sky, sun low on the horizon).

This part of the research as well - as the building of the bike shelter - points out the necessity to create a new, strong expressive identity for the LSC, where color is directly related to the production of electrical energy. The appropriate use of color in the design of buildings and the relationship between colors and energy production will be a central theme in the continuation of the research.

ABSTR ACT

This paper assesses the classrooms daylighting performance in hot and humid climate, by means of simulation in DAYSIM, considering the use of shadowed windows. The intention is to identify classrooms configurations that are still able to provide enough daylighting during the day. The study is orientated to the city of Natal, Northeast of Brazil, 5º S, on the coastal area, whose principles of passive building design emphasize daylighting and shading. An ambient with unshaded windows will be exposed to the excess of glare and thermal gains, inducing the occupants to close the curtains and turn the artificial lights on. Shading the window, it will be necessary to increase the window size to increase the diffuse light. Fortunately, these recommendations converge to create more opened architectural spaces, increasing the relation between inside and outside. However, the daylighting levels for different room depths depend on the combination of opening size and performance of the external shading. A classroom was modeled, simulated and analyzed, considering the combinations of three size openings (20 %, 40 % and 60% of window-to-wall ratio), four main façade orientations (North, South, East and West), and seven types of shading (horizontal overhang, drop edge overhang, 5º sloped overhang, horizontal overhang with side protection, horizontal overhang with three louvers, double horizontal overhang, double horizontal overhang with three louvers). Analyzes based on the useful daylight illuminance (UDI) showed limitations due to the occurrence of glare, caused by diffuse daylight next to the window. Detailed simulations confirmed a high level of influence of the combination of sky visible fraction and openings in the daylight performance.

Keywords: Daylighting, window-to-wall ratio, shading device.

INTRODUCTION

Despite the daylight availability in Brazilian cities, there are no recommendations for classrooms. This paper aims to discuss the daylight potentials in Natal. Natal, Northeast of Brazil, 5º of latitude, has great availability of diffuse light, but, according to the climate file, there is a lot of annual and daily variability in the daylight distribution. The diffuse light also causes glare, so it is important to design a shading device that also protects from this type of solar radiation. The hour of glare incidence depends on the orientation façade. The north and south façade receives solar radiation during almost the entire day, while the east façade has a better daylight distribution during the morning, and the west during the afternoon. This daily variation influences directly in the choice of the shading device. Façade orientations with fewer fluctuations can have a satisfactory daylight distribution with static shading devices, but façade orientations with more oscillations must have a dynamic shading device with manual or automatic control of the blinds and even of the lighting if it's necessary the integration between daylighting and electric light.

Mardaljevic and Nabil introduced (REINHART, MARDALJEVIC *et al.*, 2006, p.16) a dynamic daylight performance based on workplane illuminances, which determines when the daylight levels are 'useful' "for the occupant, that is neither too dark (100lux) nor too bright (2000lux). The upper threshold is meant to detect times when an oversupply of daylight might lead to visual and/thermal discomfort.”

Mardaljevic (MARDALJEVIC, *et al.*, 2011, p.5) on his study for daylight metrics in residential buildings suggests that “the occurrences of illuminances greater than 3,000lux (i.e UDI-e) should not, by design, be eliminated altogether, and that moderate occurrence may in fact be beneficial. What exactly the “optimum” levels of exposure might be is not yet known.

METHODOLOGY

The research method consists in a daylighting impact quantification of architectonical characteristics. The method consists of two approaches into two groups. There are variations in relation to the window-to-wall ratio (WWR), façade orientation and shading devices . From the behavior of the results of the first phase it was decided to make a refinement of the shading device geometry and the façade orientation. The procedures comprise the determination of hypothetical and representative models with different configurations, simulated in Daysim software (REINHART, 2010), which results are processed in spreadsheets developed specifically to complement the available metrics in Daysim, as shown in **Figure 1**.

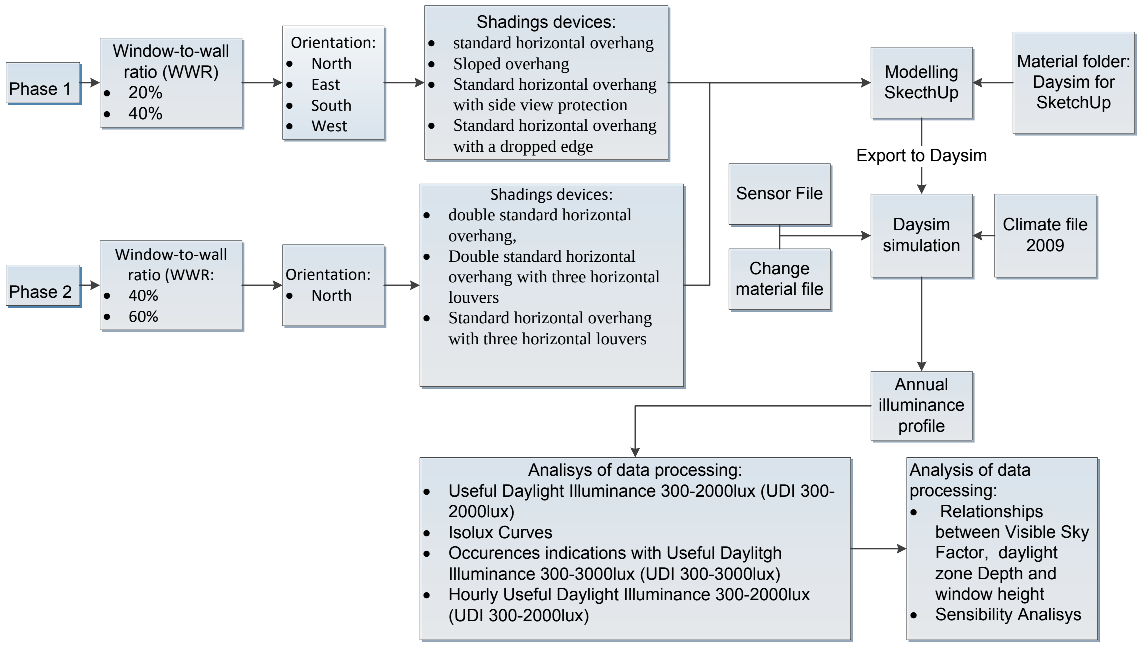

Figure 1 Research method steps.

The modelling concerns the input parameters of Daysim simulation software and presents the phases, procedures and sources detailed. The Daysim software was chosen due to the dynamic simulation, high processing speed, acceptable operationalization, outputs compatible for daylighting metrics processing and assessment.

Modelling

In the absence of a council law or guide for educational building, the model’s characteristics were obtained from the “Fundescola” legislation (FUNDESCOLA, 2002), which prescribes recommendations for schools projects. The cases analyzed are based on a common case, from which variations are created. The common features of all models are a classroom with dimensions of 7.20 m x 7.20 m. The simulations were realized with the empty room, without the distribution of the desks. The specularity properties used in this research were previously determined in the folder “Daysim for Sketch Up”, in the Daysim software.

1. Walls: 88% of reflectivity.
2. Ceiling: 88% of reflectivity.

3. Floor: 88% of reflectivity.
4. Openings: single pane glass with a visible transmittance of 90%.

The base case variations concern size of openings, façade orientation and shading devices, modelled in Sketch Up and exported to Daysim. There are three sizes of openings, characterized by Window-to-wall ration (WWR) of 20%, 40% and 60%.

Simulation

The Daysim simulation process consists of the input data, the simulation and the output data. The input data concerns climate file, modelling, sensor file, Daysim material database. The output data concerns daylight autonomy output file, daylight coefficient file, daylight factor output file, glare profile, annual illuminance profile, internal gains file for coupling with thermal simulations, and useful daylight illuminance. The annual illuminance file data was converted in percentages of useful daylight illuminance between 300-2000lux. The simulation process consisted of two phases:

1. Phase 1: classroom (7.20 m x 7.20 m), with window-to-wall-ratio (WWR) of 20 % and 40 % and shading devices, such as horizontal overhang, sloped overhang, horizontal overhang with side view protection, horizontal overhang with a drop edge, and light shelves in half or the models with WWR 40%, as shown in figures

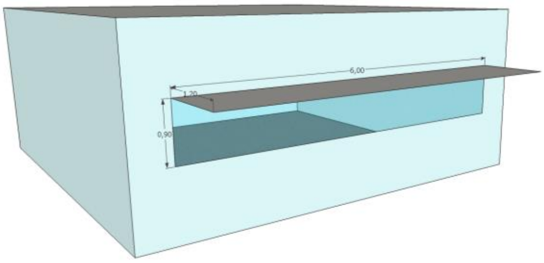

Figure 3 Horizontal overhang with WWR of 20%

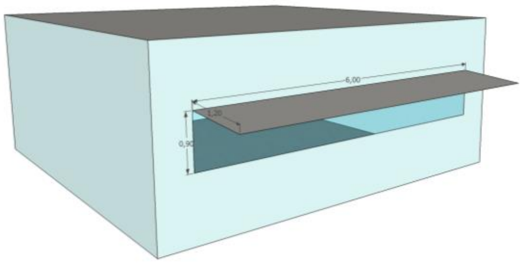

Figure 4 Sloped overhang with WWR of 20%

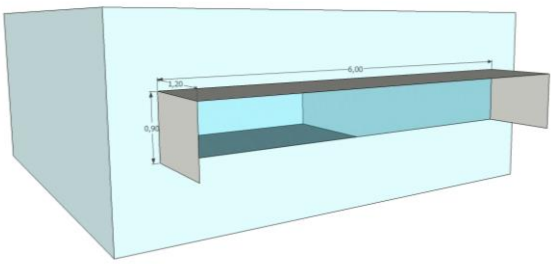

Figure 5 Horizontal overhang with side view protection with WWR of 20%

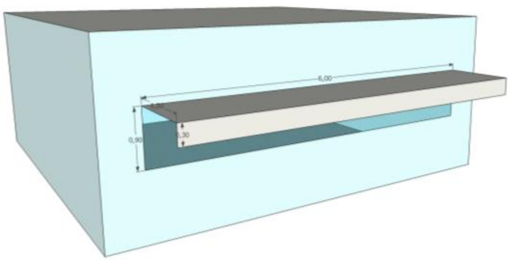

Figure 6 Horizontal overhang with drop edge with WWR of 20%

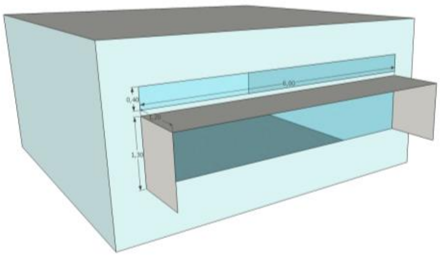

Figure 7 Horizontal overhang with WWR of 40%

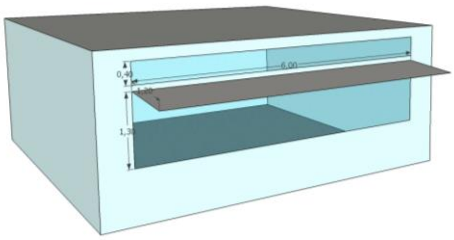

Figure 8 Sloped overhang with WWR of 40%

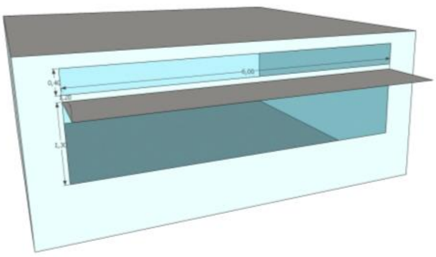

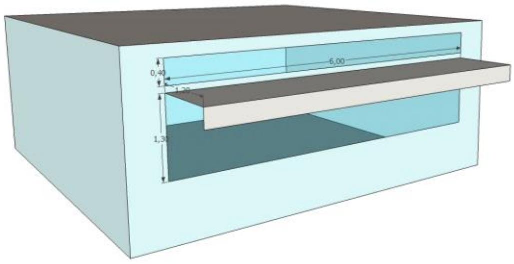

Figure 9 Horizontal overhang with side view protection with WWR of 40%

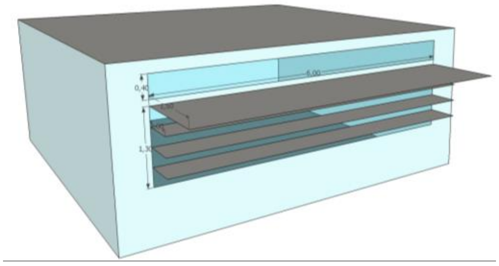
Figure 10 Horizontal overhang with drop edge with WWR of 40%

2. Phase 2: classroom (7.20 m x 7.20 m), with window-to-wall-ratio (WWR) of 40 % and 60 % and shading devices, such as double horizontal overhang, double horizontal overhang with three horizontal louvers, horizontal overhang with three horizontal louvers, besides the use of light shelves in half of the models;



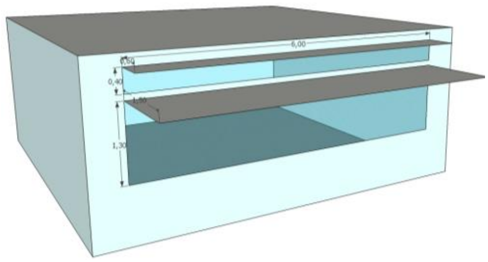


Figure 11 Double horizontal overhang with three louvers with WWR of 40%

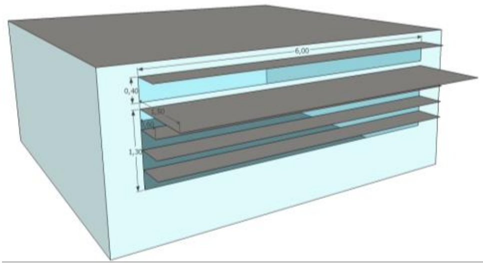
Figure 12 Double horizontal overhang with WWR of 40%



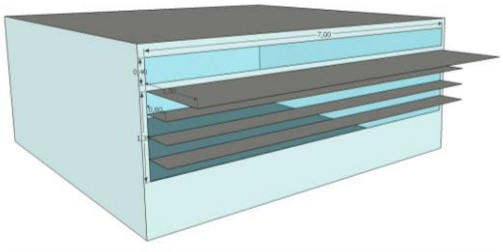


Figure 13 Double horizontal overhang with three louvers with WWR of 60%

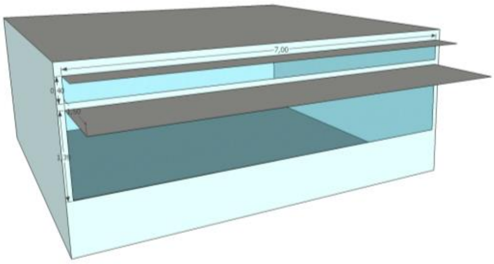
Figure 14 Horizontal overhang with three louvers with WWR of 60%



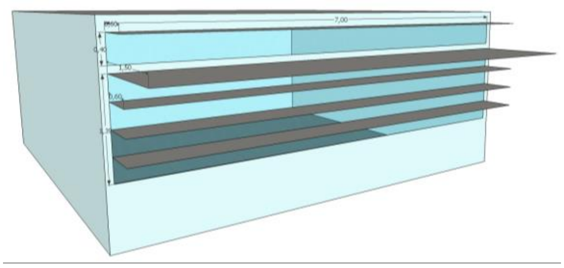


Figure 15 Double Horizontal overhang with WWR of 60%

Figure 16 Double Horizontal overhang with three louvers with WWR of 60%

The calculation of the sensor file is based on the standard NBR 15215-4 (ABNT, 2005, p. 6 e 7), which determines the number of the sensors through an equation that relates the width, depth, and height between the work plane and the topo of the window. The sensor file for WWR 20% had 36 sensor points and for WWR 40% and 60% had 16 sensor points.

Data processing

The data processing generated the following products: illuminance curves, useful daylight illuminance 300-2000lux (UDI 300-2000lux), isolux curves, hourly useful daylight illuminance 300-2000lux (UDI 300-2000lux) and occurrences indications with Useful Daylight Illuminance 300-3000lux (UDI 300-3000lux). The summer and winter solstices illuminance curves contribute to assess the daylighting distribution and the glare intensity, for each line of sensors, for each hour determined in the occupancy profile. The lower threshold of the Useful Daylight Illuminance was calculated according to the minimum illuminance level for classrooms prescribed in the Brazilian electric light regulation (ABNT, 2013, p.20), and the upper threshold was calculated for 2000lux according to Mardaljevic and Nabil (2005, apud REINHART, MARDALJEVIC *et al.*, 2006, p.16). The occurrences indication was calculated for a Useful Daylight Illuminace between 300-3000lux, according to the indication of Mardaljevic (2011, p.5). This last interval was calculated to test the improvement of daylight performance with the modification of the upper threshold.

The useful daylight illuminance was generated from the annual illuminance profile output, with illuminance data for each sensor points and each 1/12 per hour. The UDI 300-2000 lux spreadsheet was converted in isolux curves, as shown in **Figure 3**, generated in Surfer software by the Krigging method. LANDIM, MONTEIRO *et al* (2002, P.5) present a table summarizing the main interpolation methods. According to the authors, each method presents advantages and disadvantages, according to four categories: fidelity to the original data, smoothness of curves, computing speed, overall accuracy, as shown in **Table 3.** The Krigging method had the best accuracy and fidelity. The graphic represents the daylight distribution, easily understandable, as shows in **Table 2**.

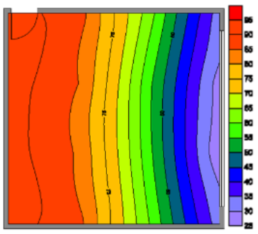

Figure 3 Isolux curves from east orientation, 40% WWR, horizontal overhang, with light shelf

Table 2 Interpolation methods (LANDIM, MONTEIRO *et al.*, 2002, p.4)

Algorithm	Fidelity to the original data	Smoothness of curves	Computing speed	Overall accuracy
Triangulation	1	5	1	5
Inverse distance	3	4	2	4
Surface Trend	5	1	3	3
Minimum curvature	4	2	4	2
Krigging	2	3	5	1

Scale	Qualification
1	Best performance
5	Worst performance

The hourly useful daylight illuminance 300-2000lux (UDI 300-2000lux), as shown in **Table 3 and Figure 4**, is an hourly occurrence for each day, based on the occupancy profile, from 08:00h to 16:00h. The occurrences indications with useful daylight illuminance between 300 and 3000lux, as shown in **Table 4**, indicates the percentage of glare, comfort and low illuminance for each zone. MARDALJEVIC et al. (2011, p.5) suggest that illuminances above 3000 lux should not be discarded, because the optimal daylight exposure level is still unknown, and the thermal gains can be mitigated by the use of an air-conditioner system.

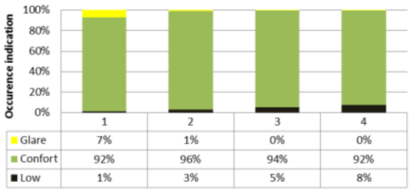
Table 4 Occurrences indications with useful daylight illuminance 300-3000lux, north orientation, 60% WWR, without light shelf



RESULTS AND DISCUSSION

Based on the illuminace curves, the light shelves perform better as internal shading. The light shelves didn't increase the daylight zone, or contribute to uniform the illuminance curve, but the glare incidence in the first row of sensors was reduced, in general, as shown in **Figure 5 and 6**, in the first graphic the highest illuminance curve was next to 3500lux, in the second case the highest illuminance level was 5000lux. The light shelf use reduces the glare incidence at the first row of sensors for almost a half.

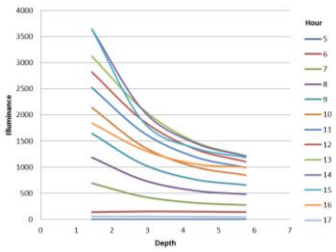


Figure 5 Illuminance curve for horizontal overhang, west orientation, 40%WWR, with light shelf

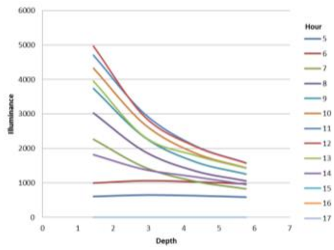

Figure 6 Illuminance curve for horizontal overhang, west orientation, 40%WWR, without light shelf

In general all of the 20% WWR models have an accentuated daylight curve close to the opening, and no glare occurrence, **Figure 6**, the daylight zone depth was smaller than the half of the room. The sloped overhang model had the best daylight distribution for east orientation, with 20% WWR. Other orientations produced UDI between 80% and 64% in the first row of sensors. The daylight zone depth was 1,95m, for a 90% UDI, for east orientation. The 40% WWR models simulated at the first phase have daylight zone depth equals de room depth, however with glare occurrence at the first row of sensors causes an UDI lower than 75%, as shown in Figure 7.

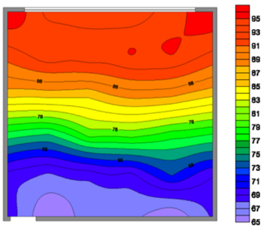

Figure 6 Isolux curves for sloped overhang, north orientation, 20% WWR, without light shelf

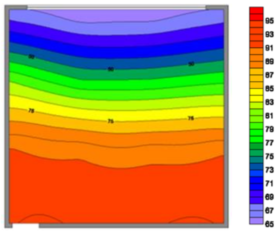

Figure 7 Isolux curves for sloped overhang, north orientation, WWR 40%, without light shelf

The first phase simulations demonstrates glare incidence in the first row of sensors, mainly for the 40% WWR (11h illuminance curve: highest illuminance value= 2000lux, lowest illuminance value= 750 lux), and high illuminance gradient for 20% WWR (11h illuminance curve: highest illuminance value= 1200, lowest illuminance value= 450lux), as shown in **Figures 8 and 9**, the daylight distribution varies during the day.

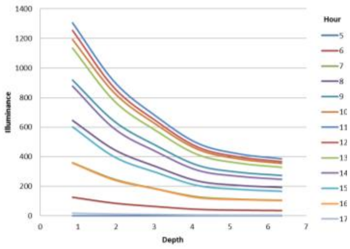

Figure 8 Illuminance curve for horizontal overhang with drop edge, WWR 20%, without light shelf, south orientation

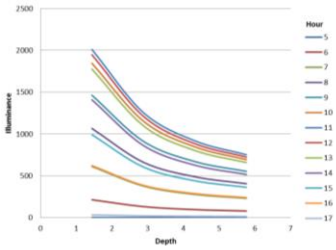

Figure 9 Illuminance curve for horizontal overhang with drop edge, WWR 40%, without light shelf, south orientation

The UDI table shows the values of UDI for the different sensors, according to the sensors map. It was detected a 90% UDI only for the period between 9:00h and 14:00h for east orientation model, as shown in **Table 5 and Figure 10.**

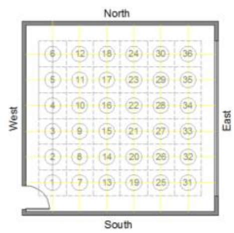

Figure 10 East orientation map of sensor

The second simulation phase was realized with 12 different models, only for the north orientation, with two openings size (the 40% and 60% WWR), three different shading devices (horizontal overhang with three louvers, double horizontal overhang, double horizontal overhang with three louvers) and with or without light shelves.

The double horizontal overhang had a similar effect to light shelf, reducing the glare incidence in the first row of sensors. The models' daylight distribution with no light shelves performed better with 40%WWR; the 60% WWR had a reduction of a glare incidence in first row of sensors. To decrease this incidence and improve the daylight distribution, it was inserted internal shading device in the light shelves. The 40%WWR model accentuated the illuminance gradient, reducing the daylight zone depth, as shown in **Figure 11 and 12.** The 60% WWR model resulted in a better daylight distribution and low glare occurrence, as shown in **Figure 13 and 14.**

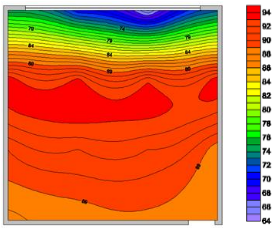

Figure 11 Double overhang with three louvers, WWR 40%, north, without shelf

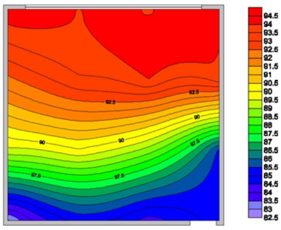

Figure 12 Double overhang with three louvers, WWR 40%, north, with light shelf

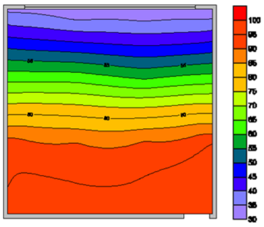

Figure 13 Double overhang, WWR 60%, north, without shelf

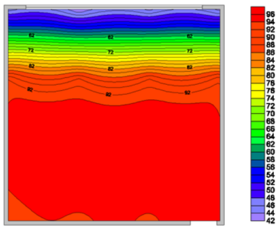

Figure 14 Double overhang, WWR 60%, north, without light shelf

The occurrence indication detects the glare occurrences in a UDI between 300-3000lux for each daylight zone. The daylight zone distribution was done according to the sensor map, which has some variations according to the façade orientation. Each table bar refers to one daylight zone at the sensor map, according to the figures 15, 16, and 17. The change of the UDI upper threshold to 3000lux had increased the occupants' comfort level frequency, mainly in 40% WWR models. The 20% WWR model with the best performance was the horizontal overhang with the best comfort indication in the daylight zone six (67%), comparing to the other models that had lowest indications (sloped overhang - 61%, horizontal overhang with side protection – 59%, horizontal overhang with drop edge – 49%), as shown in **Table 6.** The 40% WWR opening with the best daylight distribution was the double horizontal overhang with three louvers with light shelf had a first row of sensors with a glare indication of 0%, as shown in **Table 7**. The 60% WWR opening with the best daylight distribution was the double horizontal overhang with three louvers and light shelf had the first row of sensors with glare indication of 1%, as shown in **Table 8**. In the second phase models the glare occurrence was reduced or eliminated in both size of openings (40% and 60% WWR), but for the 40% WWR there was a bigger reduction in the daylight zone six than in the 60% WWR (81% - in the first, 87% in the second).

CONCLUSION

The analysis method demonstrated that a single criterion is not enough, leading to combine other resources, such as illuminance curves for each time of the day, for each month of the year of the climate file, calculation of UDI between 300 and 2000lux to obtain a flexible and suitable interval, visible sky factor quantification for each opening and shading system, introduction of occurrences indications with UDI between 300 and 3000lux

The performance comparison among different fenestration systems and orientations indicates few differences, with UDI varying between 90% to 100 %, while the annual and daily daylight variability are very significant. The shelves were used as an internal shading system, avoiding the glare in the first row of sensors, and reducing the daylight zone. This system was suitable to 60%WWR and the glare eliminated at the first row of sensors while 40% WWR has reduced 50% of the daylight zone.

Each WWR had different daylight performances: In the phase 1 the 20% WWR didn’t have glare occurrences, but the daylight curve had a high declination after the daylight zone of 3,50m. In the phase 1 the 40% WWR had glare occurrences in the first row of sensors, which was reduced with the use of louvers. In the phase 2 the 40% and the 60% WWR had the glare occurrences reduced or eliminated in the first row of sensors. The daylight zone of 40% WWR had a variation between 3,54m and 4,75m and the daylight zone of 60% WWR had achieved a daylight zone of 7,20m.

Joon-Ho Choi, PhD, LEED AP
[University of Southern California]

ABSTRACT

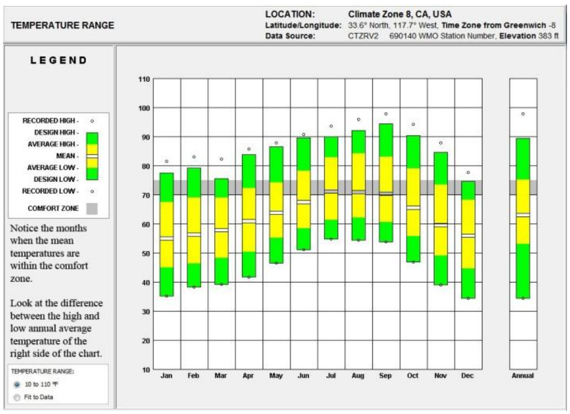
Population growth, city sprawls, increase of households and overuse of resources, affect the environment and impact greatly the energy use. About 40% of the energy demand in US and Europe goes to the buildings, with residential exceeding the commercial. Building codes and energy standards aim to reduce the consumption by setting minimum standards. "Architecture 2030" and "Europe 2020" target a higher reduction. Energy simulations are the first step towards the goals. Energy code compliance software evaluate energy and environmental performance of a building by approving or rejecting it according to the estimated outcome. Variations of materials, building strategies and systems affect the energy use and consequently its efficiency. How do two different compliance code software programs, evaluate a same building performance in a Mediterranean climate? For this study, a comparative analysis using two code compliance software: Energy Pro and iSBEM-CY has been conducted. A two story simple family detached house was selected with two construction design options: (a) high thermal mass and (b) low thermal mass in the sub-tropical Mediterranean climate. For this selected climate condition, Los Angeles in California and, and Larnaca in Cyprus were chosen in the study. Through this comparison the variations have been examined whether they meet both codes and ultimately the most energy efficient design option for each region has been identified. Differences in the inputs, outputs and parameters between the two software programs which are estimated to have impacted the results have been identified and described.

INTRODUCTION

Building energy usage accounts for 40% of the total energy consumption in the U.S. (DOE, 2008). Architecture 2030 and Europe 2020 target the reduction of the building energy sector by 50% to 100% (i.e., net zero energy). Federal and State energy codes and requirements become more stringent to meet the energy reduction target. Although the number of households increased in the U.S. from 1980-2009, the average household energy consumption actually decreased (RECS, 2013). In contrast, household energy consumption in the EU-27 increased by 7.5% (EEA, 2012) between 1990 and 2009.

Energy consumption in buildings has a major impact not only on the environment but also on building occupants' environmental comfort. Since 90% of the modern people spend their time indoors (EPA, Report to Congress on indoor air quality: Volume 2. EPA/400/1-89/001C, 1989), thermal comfort and indoor environmental quality have a great impact on people's health and productivity. Therefore, the design of a building should consider the climate conditions. The Mediterranean climate in both cities studied, Los Angeles **as shown in Figure 1** and Larnaca **as shown in Figure 2**, is sub-tropical, with the warm to hot summer and mild winter. Both climates are semi-arid.

Climate change, urban sprawl, and heat island effect have increased building energy demands. Depending on the heating and cooling seasons, temperature swings between indoor and outdoor environment vary. More specifically, and from a climatic perspective, the parameters that affect this fluctuation are humidity, solar radiation, outdoor temperature, etc. For indoor conditions, the number of occupants, their activities, lighting, and equipment all contribute to the energy consumption. High peak loads, especially during the summer, can result in the use of bigger mechanical systems. Consequently, the amount of energy use increases and operating costs follow accordingly. A major building component which affects buildings energy usage and its efficiency is its envelope. Therefore it is necessary to study the climate conditions of every site location and to identify the most appropriate design strategies for it.



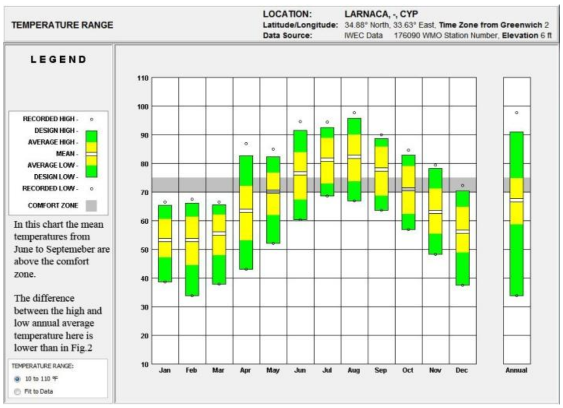


Figure 1 Annual temperature range (°F) for California climate zone 8 from Climate Consultant.

Figure 2 Annual temperature range (°F) for Larnaca, Cyprus from Climate Consultant.

The annual average and monthly temperature ranges of the two locations **are shown in Figures 1** and **Figure 2**. Mean temperatures in Los Angeles (Figure 2), located in California climate zone 8 are within the comfort zone in July, August, and September. The rest are below the comfort zone and heating is required. The average annual ΔT in Los Angeles is 21°F (6.1 C°) with the highest recorded temperature at 98°F (36.6 C°) and the lowest at 34°F (1.1C°). In Cyprus, only May and October provide mean temperatures within the comfort zone. From June to September there is a need for cooling. The rest of the months show a heating demand. The average annual ΔT in Larnaca is 7°F (13.8 C°) with the highest recorded temperature at 98°F (36.6 C°) and the lowest at 34°F (1.1 C°).

HIGH & LOW MASS BUILDING PERFORMANCE IN MEDITERRANEAN CLIMATES

Historically, buildings in Mediterranean climates were constructed with high mass materials. Specifically in Cyprus, for the vernacular architecture, stone and adobe blocks were mainly used in the structure. Nowadays, the majority of the residential buildings are constructed with concrete and brick. Controversially, in California’s dwelling history, buildings tended to be of lightweight construction, primarily wood. Until today, the tradition of lightweight buildings is still the common practice for residences. Materials with high thermal capacity absorb solar radiation during the day and release it during the night. This property of the materials has been used in architecture as a passive strategy to achieve desired indoor temperature levels and comfort. By contrast, materials with low thermal capacity have a limitation in storing heat. As a result, this thermal phenomenon can cause the shift of peak temperatures between indoors and outdoors very quickly, i.e. thermal lag is reduced. This study examined the properties and performance of the typical high and low mass envelopes in a residential building for the Mediterranean climate of Los Angeles and Larnaca. Thermal mass is classified into (a) exterior thermal mass- defined as the mass of the elements which are exposed to the exterior environment, and (b) interior thermal mass- defined as the mass of the elements inside the envelope such as interior walls, floors, chimneys, ceilings, etc. (Chi-wai, 2003). In this study, thermal mass refers to the constructed building elements, both interior and exterior, excluding any movable objects such as furniture.

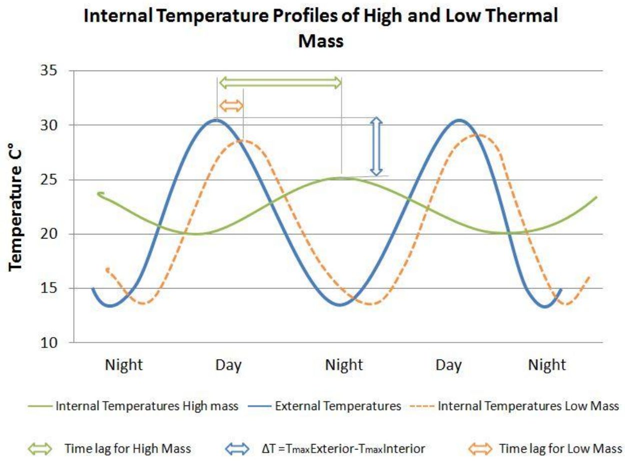

Figure 3 Internal temperature profiles of high and low levels of thermal mass.

High Mass - Cyprus

Residential buildings in Cyprus are primarily constructed out of high mass materials. The building structure is made out of reinforced concrete and the non-bearing walls with brick. There are two main variations for the wall assemblies in the iSBEM-CY code compliance software:

1. Double brick wall 1'(30cm) thickness with 2"(5cm) air gap in the middle, U-value 0.198Btu/ $ft^{2°}F$ (SI: 1.29W/ m^2K).
2. Double brick wall 1'(30cm) thickness with 1"(2.5cm) air gap and 1"(2.5cm) extruded polystyrene U-value 0.107Btu/ $ft^{2°}F$ (SI: 0.608 W/ m^2K).

According to the Cypriot building code only the second material assembly (b), complies with the energy rating standards. A wall with higher U-value than 0.149 Btu/ $ft^{2°}F$, even if it has such a relatively low insulation-performance, is allowed when the thermal mass is adopted as a passive strategy for heating and cooling. These wall assemblies are both provided in the Cypriot code compliance software.

Low Mass – California

For a California residential building, the wall assembly was preselected from HEED, Scheme 1: the auto generated code compliance energy model was adopted:

1. Stucco or Face brick on 2x4 Wood studs at 16" with Plaster board interior with the U-value 0.09 Btu/ ft2°F (SI: 0.511 W/ m^2K).

METHODS & APPROACH

For this study, a single family detached house of 1,600 sq.ft. (148.64m^2) was initially designed in HEED (Home Energy Efficient Design). HEED is an energy design tool primarily used for low rise residential buildings. For the performance comparisons, two building energy models were used in each location, Los Angeles and Larnaca: high and low mass .During the study it was observed that in HEED the Larnaca climate was translated into California climate zone 8. The energy performance of the high mass simulation showed an annual average EUI of 28.07 kbtu/sf/y (88.55 Kwh/m^2), and an EUI of 34.81 kbtu/sf/y (109.81 Kwh/m^2) was estimated for the low mass. From this comparison the first drawn conclusion is that the high mass buildings are more efficient overall throughout the year than the low mass for the Mediterranean climate. The next step was to use EnergyPro to identify whether the models comply with the California energy code, Title 24. Similarly, the models were designed to the corresponding Cypriot code compliance software iSBEM-CY. The generated outcomes from the two code compliance software were compared. Software similarities and differences were found and described.

EnergyPro

EnergyPro is one of the California code compliance (Title 24) energy analysis program and one of its potential is the energy verification for low-rise residential buildings and whether they comply with the energy code. For the purpose of issuing a certificate based on the code, the software is originally designed only for California climates, and the software adopts DOE-2 for a simulation engine. The Larnaca climate files were not able to be used per the software notification: Larnaca does not have a valid California Climate Zone for the California Title 24 calculations. In order to run the models the Los Angeles weather file Climate 8 was used. All the building elements were checked and verified in the software. The models were designed as single zone for more accurate calculations of the thermal mass impact to their energy use intensity.

High and Low mass building in EnergyPro. EnergyPro assumes certain thermal mass characteristics for the calculations. All residential buildings are considered to contain a pre-set amount of “light” thermal mass. Heavy thermal mass is modeled based on the conditioned area of slab floor as 20% exposed 80% of it as rug-covered slab and 5% of the non-slab area as exposed 2 inch thick concrete (EnergySoft, 2011). Concrete floors that are covered by carpet are not considered exposed thermal mass.

For the calculations of the high mass building loads, all the required values were taken from the Cypriot code and converted to IP units. The material properties selected in this study are listed in Tables 1 and 2. Walls, roof and floor had to be customized in order to generate the same U- values. The U-values were managed to be adjusted 95%. One of the of the software’s limitation is that customizing high mass components for Heat Capacity (HC) is not possible. A default HC condition of the selected wall type was adopted in this study, while some of the other elements were changed to “0” as shown in Table 2.

Performance of the thermal mass in EnergyPro. Using Energy Pro, an experiment was made before the residential building was modeled. The scope was to identify whether the software encountered the thermal mass impact to the energy use intensity by changing the settings of the thermal mass for roof, walls and floor. In the software two available options exist regarding the thermal mass and how it affects the energy calculations, these are: None or Mass Type. Under Mass type these variations are available: Adobe, Concrete heavyweight, Concrete lightweight, Masonry partial grout, Masonry solid grout, Wood solid logs and Wood cavity wall. After selecting the Mass type the option of having it exposed (as pre-mentioned above) or not is available. Furthermore, the thickness of the mass can be imputed.

For the testing, a Masonry partial grout wall was used, and the heavyweight concrete mass was selected for the roof and floor. Two variations were made. **Figure 4** shows the performance of the same envelope “with non exposed mass” and “with exposed mass”. The form of the line demonstrates the effect of the thermal mass to the envelope’s efficiency. The smooth curve illustrates this transition and decrease of the EUI as expected. During the experiment, none of the other settings in the model were changed. The total ΔEUI between the 6” (0.15m) non-exposed to 30” (0.76m) thickness exposed is about 6kBTU/sq.ft./y (18.92 Kwh/m^2).

The next step was to examine the effect of the thermal mass to the overall building’s performance. In this case all the building systems were used as per the code requirements. The efficiency of the systems is listed in Table 1. Similarly, two runs were made, with the mass non-exposed and exposed. **As shown in Figure 5**, it is clear that the exposed thermal mass contributes to the reduction of the energy loads and can be calculated in EnergyPro.

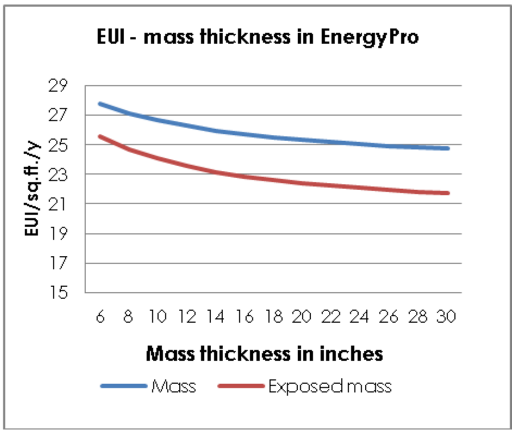

Figure 4 Relation of EUI and thickness.

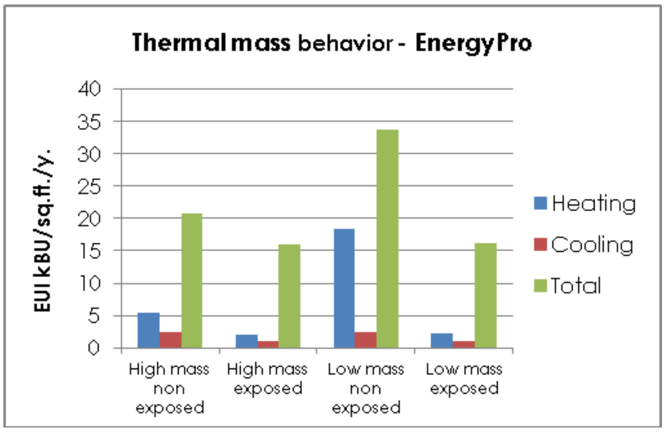

Figure 5 Thermal mass behavior in Energy Pro.

iSBEM-CY

For Cyprus, the corresponding code compliance software is iSBEM, which stands for interface of Simplified Building Energy Model. The program is based to the British SBEM software and BRE rating system. Since the law of certifying buildings' performance launched in 2010, the iSBEM-CY is new and consequently has some limitations. The rating system of certifying buildings has a range from A to F. A building will be certified only if meets at least the "B" rating score of EUI: "A" < 15.99 kBtu/ ft2, "B" from 16 kBtu/ft2 to 31.99 kBtu/ ft2, "C" from 32 kBtu/ ft2 to 46.99 kBtu/ ft2, "D" from 47 kBtu/ ft2 to 63.69 kBtu/ ft2, "E" from 63.7 kBtu/ ft2 to 94.99 kBtu/ ft2 and "F' > 95 kBtu/ ft2.

High mass building in iSBEM-CY. For the design of the model that meets the code, the building elements with the highest U-values were used. This was made for two reasons:

1. To test if the model will get a certification.First numbered item
2. To compare its energy use intensity with the model in EnergyPro Second numbered item

In iSBEM-CY as mentioned at 2.1 High mass – Cyprus, only two available wall assemblies exist: the one with higher U-value than the code requirement and one that meets the requirements. In the user's manual there was no reference for the one that does not apply. The assumption for the first type is that it's being used for existing buildings. If none of the above choices is desired, alternatively someone can input its own U-Value. Similarly, the "Cm" setting, which is the Heat Capacity of the element, can be modified. There is no option for changing the thickness as in EnergyPro. In the same way all the envelope elements such as roof, floors, doors and windows, can be adjusted. Regarding the effect of thermal mass in the iSBEM-CY, it is not clear yet. More details are given at 3.3 Comparison of performance and 3.4 Comparison of software.

Low mass building in iSBEM-CY. For the design of the low mass code compliance building from California, all the values and units were converted from IP to SI. The U-values and heat transfer coefficient were inputted. Therefore, walls, roofs, floors, doors, were only assigned by these properties while glazing had additionally the Tvis (L-solar) and SHGC (T-solar). Table 2 shows all the values and units required for the high and low mass code compliance residential buildings of Los Angeles and Larnaca.

COMPARISON OF PERFORMANCE

Overall four runs were made in the two software, EnergyPro and iSBEM-CY: In EnergyPro: High mass that meets the Cypriot code and, Low mass Title 24 code compliance. In iSBEM-CY: High mass that meets the Cypriot code and Low mass Title 24 code compliance. For the highest possible accurate results the same HVAC and domestic hot water (DHW) systems were used as shown in Table 1.

Table 1. Building Systems and Efficiency

System	Type	Efficiency
DHW	Gas Boiler	59% Energy Factor
Heating	Gas Furnace/Boiler	78% AFUE
Cooling	Split System	SEER 13, EER 13

In EnergyPro, model (2) was the low mass Title 24 code compliance. The goal was to see if a residential house which complies as “B” performance to the Cypriot code would comply to Title 24. Indeed, the runs showed that the model did meet the California code requirements.Similarly, model (4) was designed in iSBEM-CY, with the standards of the California code. In this case, the model met the requirements of the Cypriot code and was classified as “B” in its performance.Table2 shows the inputs used in the two software and the modifications that were made in order to abridge the models between their values as much as possible. In the Building components “h/m” stands for the propertied of the high mass energy model, and “l/m” for low mass.

Table 2. Building Component Properties

Building Compo nent	EnergyPro U-value Btu/h ft2°F	EnergyPro HC Btu/ ft²°F	iSBEM-CY U-value Btu/h ft2°F	iSBEM-CY HC Btu/h ft2°F
Wall (h/m)	0.148	16.3	0.149	5.145
Wall (l/m)	0.095	0	0.095	0.10
Roof (h/m)	0.131	0	0.132	11.025
Roof (l/ m)	0.028	0	0.028	0.10
Floor (h/ m)	0.36	0	0.35	11.368
Floor (l/m)	0.034	0	0.034	0.1
Door (h/ m)	0.60	0	0.669	0.49
Door (l/ m)	0.50	0	0.50	0.10
Glass (h/m)	0.67	Tsolar=SHGC=0.76 Lsolar=Tvis=0.80	0.669	Tsolar=SHGC=0.76 Lsolar=Tvis=0.80
Glass (l/m)	0.669	Tsolar=SHGC=0.76 Lsolar=Tvis=0.80	0.40	Tsolar=SHGC=0.40 Lsolar=Tvis=0.49

The energy use intensity of the models in the two software programs **is shown in Figure 6**. As illustrated, the high mass residential building in EnergyPro is more efficient that the low mass. In contrast, in the iSBEM-CY the low mass is shown to be more energy saving. The assumption for this difference lies in two possible reasons:

1. The iSBEM-CY does not calculate in the same way thermal mass as the EnergyPro High mass that meets the Cypriot code.
2. The lack of the elements thickness customization when changing the U-value and heat capacity of the assembly might not reflect the performance respectively.

The difference between the two software results in performance is beyond 100% in EUI **as shown in Figure 6.** The outocomes were expected vart but the disparity had not been anticipated to be so high. The results were estimated to differ due to the factors **shown in Table 3**. The software engines for the performance calculations differ. EnergyPlus has a higher resolution of inputs than iSBEM-CY, which is a simplified building energy modeling tool taking many parameters as defaults. Therefore the algorithms for heat transfer or the alculation of infiltration, radiation and conduction etc. are different; but they have not been examined for the research. The weather files used in the software differ and their values impact the performance calculations. Geometry in this study was the same. Finally the compatibility of the file format for comparison would provide more answers but iSBEM-CY does not use or generate .gbXML files or similar; and consequently more detailed comparison between the files could not be implemented.

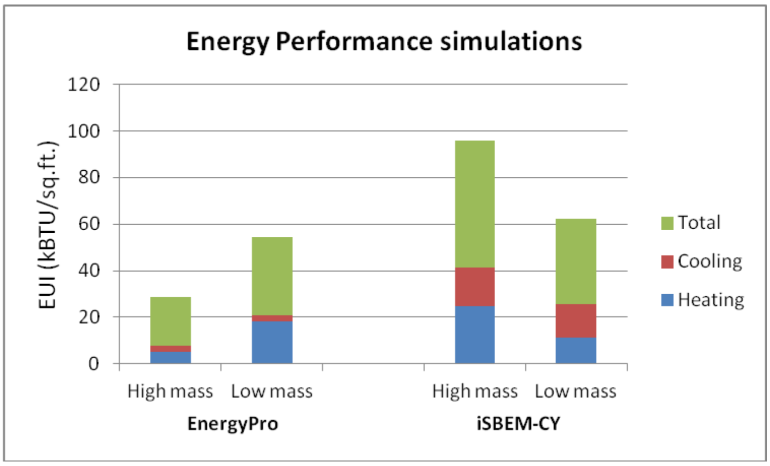

Figure 6 Energy performance simulations.

Table 3. Software input comparisons

System	EnergyPro	iSBEM-CY
Engine	DOE 2	SBEM
Weather files	TMY 3	Climate file from the software
Geometry	Same geometry	Same geometry
File type	.bld	.nct

COMPARISON OF THE SOFTWARE

A comparison among the two code compliance software has been performed. Similarities, differences and their limitations have deen identified:

Similarities

Both EnergyPro and iSBEM-CY were used for code compliance verification of residential and non-residential buildings.None of them showed a graphical representation of the building. None of the software is a design tool.

Differences

The iSBEM-CY software does not use .xml files for the model design but .nct. As a result, it was not possible to import and use the same project files between the software. Instead they had to be designed separately in the iSBEM-CY. It generates though .xml files for the official submission to the Register. The iSBEM-CY requires a SHW (Solar Hot Water) system since it is required by law. In EnergyPro the SHW is optional. For the purpose of this study, SHW was used in both cases. In EnergyPro it is not required to add an HVAC for cooling or heating. A fact which can give a better understanding of effect the buildings elements have to its performance. The two software use different units: EnergyPro uses the imperial system (IP) and the iSBEM-CY the metric system (SI). Regarding the result outputs, EnergyPro according to the EUI shows % of savings compared to the Title 24. iSBEM-CY generates the EUI and categorizes the building between the A to F range, where A the most efficient. EnergyPro and iSBEM-CY do not have the same options of adjusting the elements and building systems.

Limitations

For the iSBEM-CY, there are several settings which need to be adjusted in the Control Panel before running the program: for example, changing the "Regional and Language Settings" to United Kingdom, and changing the "User account settings" to "Never Notify". If these settings are not changed, the software will not run properly, and will fail to make the calculations and generate the reports. iSBEM-CY has a limited library of building elements and systems compared to EnergyPro. It is not currently possible to input the envelope's thickness manually. Therefore, it was not possible in the iSBEM-CY to evaluate how it calculates the effect of the thermal mass on the building's performance.

CONCLUSIONS

One of the most important findings in this study is that high mass buildings are more energy efficient in Los Angeles and in Cyprus the low mass. Taking into consideration the graphs **as shown in Figure 1 and Figure 2**, we could identify that more months are heating dominant than cooling in both locations. According to Climate Consultant, HEED and EnergyPro High mass residential buildings are more efficient than the low mass buildings in this climate. The EnergyPro and HEED results confirmed it. The Cypriot vernacular architecture and current construction materials applied also reinfornce the use of high mass materials as more efficient. Therefore, building materials with high thermal mass are suggested as a passive strategy for enhancing the building performance in this climate. The iSBEM-CY results contradicted these conclusions and consequently further studies should be carried in regards to iSBEM-CY to evaluate its outputs.

Futhermore, both the High and Low mass models passed the EnergyPro with 24% energy savings compared to Title24. Similarly, both the High and Low mass models passed the iSBEM-CY and were rated as "B" in their performance. EnergyPro counts thermal mass into its calculations. In contrast for iSBEM is not clear at what percentage its being calculated since the high mass had greater energy consumption compared to the other software. The attempt to simulate the models without an HVAC was possible in EnergyPro. iSBEM-CY cannot proceed to the calculations without an HVAC system. The assumption is that the developers of the software did not want to allow certification without an HVAC since the climate it Cyprus makes a mechanical system mandatory. Finally, Title 24 is more stringent than the Cypriot Energy code.

For Future works, a more extensive research with the iSBEM-CY software in order to obtain a clearer understanding of how the thermal mass is being perceived and calculated. Finally a comparison of the high and low mass models in other software could be used for validation of the results.

ABSTRACT

This paper describes different technological and architectural designs developed as the 2013 fall term project for the studio "Architectural Design VII" in partial fullfilment of the Architecture and Urbanism undergraduate programme belonging to the Federal University of Rio Grande do Sul, Brazil. The pedagogical aim of this project was to stimulate students to achieve high-level technological results along with expressive architectural solutions. The chosen case study was a residential unit ranging from 60sqm to 70sqm, able to house a married couple. The design brief was similar to the one adopted by the competition Solar Decathlon, held in the USA, Europe and China. The Studio methodology consisted of three steps: shape concept, performance evaluation and technological and architectural refinement. The shape concept is an exercise addressed to support the emergence of creative shapes with the contingent risk of getting unpredictable technological results; the following step consisted of the proof-of-concept of the house's energy autonomy, whereby the students were asked to demonstrate the project's electrical energy consumption and its capacity to autonomously supply at least the equivalent amount of energy. The performance tests involved evaluations related to natural lighting and thermal balance, daily and annual energy balance and reciprocally, the contribution of renewable energy and input sources such as photovoltaic cells and rainwater collection. In its final stage, the term project featured the refinement of the conceptual architectural design focusing on the integrated design of three building systems (structural, construction and installations). As a result of the term, it was observed that the adopted methodology produced reliable results for the pedagogical purpose in the fourteen projects presented, however the final stage may require more temporal importance in the schedule of the discipline.

1. INTRODUCTION

This work aims at describing the architectural design process using different technological and architectural designs developed during the 9th semester of the five year undergraduate program in Architecture and Urbanism at the Federal University of Rio Grande do Sul, Brazil. The main pedagogical aim of this term project is to encourage students to achieve high-level technological results along with expressive architectural solutions (Corrêa & Cruz, 2012). The chosen case study was a residential unit, 70 sqm, home for a married couple, and with a design brief similar to the one adopted by the Solar Decathlon (U. S. Department of Energy (1), 2014), held in the USA, Europe and China.

A previous evaluation of certain architectural solutions form the Solar Decathlon had raised the question about the limitation of sustainable homes regarding their form. Therefore, the term's challenge was to answer the question as to whether it would be possible to design an expressive architectural shape

Silvia R. Morel Correa and Benamy Turkienicz are professors at the Faculty of Architecture and Urbanism at the Federal University of Rio Grande do Sul, Brazil. Lennart B. Poehls is Ph.D student in the Program for Research and Post-graduation in Architecture of the Federal University of Rio Grande do Sul, Brazil.

while maintaining a consistent relation between form and environmental performance, specifically the balance between energy consumption and production. This assessment is based on the assumption that sustainability issues naturally cause considerable modifications in the architectural language of the designed houses. The need to use photovoltaic and solar panels, new building materials as well as assembly and disassembly techniques and last but not least, the need to optimize the architectural form in order to maximize the reception of solar radiation destined to create major implication in the final designs. It was observed that a significant number of projects featured very conventional house designs concealing the visual impact of the technical elements responsible for the environmental performance of the house. From the students' points of view, various Solar Decathlon solutions – although featuring high scores according to the competition standards - did not introduce any particular contribution regarding their respective architectural form. All this reasoning has led to the question of how to achieve a good and optimized architectural design standard along with an optimized energy performance. Consequently, the problem of how to evaluate the students' designs, when considering the consistency between sustainability issues and architectural form, arised. In order to accomplish this goal a pedagogical strategy has been set whereby a) the students were asked to start from an architectural vocabulary inspired by sustainability issues such as natural forms used for solar radiation capture, b) the students were submitted to an evaluation system which provides them with a permanent assessment during their design process in relation to the studio's theme, i.e. the consistency between sustainability and architectural form, among others. The 9th semester studio methodology consisted of three sequential steps or exercises: i) the development of the shape concept, ii) a proof-of-concept including computational performance evaluations of the proposed architectural shapes and iii) final technological adjustment.

The remaining paper is divided into four parts: In the first part, the three stages are described. The second part presents the evaluation system and its results are analysed. In the fourth and last part, some conclusions are drawn in order to clarify the limitations and point out perspectives of the adopted methodology.

2. THE THREE STAGES METHODOLOGY

2.1 Development of the Shape Concept

The shape concept exercise was intended to support the emergence of expressive shapes with the contingent risk of provoking unpredictable structural solutions and energy performance results. Other issues, such as gray water collection and treatment, energy consumption and building materials, were – at this stage – considered peripherally as indicated by the structured list of requirements establishing the main design goals to be developed at certain points of time during the term.

This first phase was subdivided into two exercises: in the first one, the students analysed one entry to the Solar Decathlon competition and, in the second exercise, the students developed their own shape concepts. The analysis of the competition's house was divided into four topics.

Varios aspects have been highlighted during the teaching, the first among those was the architectural language and to what extend it expressed the materials, technologies, equipments and strategies for the production and conservation of energy as well as the achievement of environmental comfort. The question is: Are the "green" characteristics visible or not? These features may exist but they might not be visible or distinctive.

The second topic was about building technology and implies prospecting two factors: on the one hand the description of basic structural characteristics of the building, on the other hand the identification of novel components not found in conventional constructions. Building technology also involves materials, which are used for structure, waterproofing, foundations, thermal insulation, internal and external coating. The student should describe aspects of employed technological innovation in materials by linking these factors to corresponding goals, such as energy conservation, thermal comfort, cooling, among others.

The third issue involved the analysis of passive strategies and materials proposed for thermal insulation on horizontal and vertical planes. The shape, size, position and orientation of the openings and sealing elements also should be presented and the students were supposed to verify the way each element contributes to the thermal and visual comfort of the analysed project.

The fourth focus, denominated Ergonomics, was related to the technological innovations articulated throughout the arrangement of spaces and the flexibility offered by furniture components. This variable was intended to assess different levels of ease of use during the operation of spaces such as kitchen, bathroom, living room and bedroom by the end-user.

The second exercise was refered to as “conceptual shape”, which would be used by the students during the term’s subsequential time. Its purpose was to encourage the students to research more creative concepts, in a process which may require taking a step backward to achieve the principles of sustainability. The use of materials, technologies, devices and strategies intended to produce and maintain energy, as well as achieving a suitable level of environmental comfort may generate a relative tension between the architecture of the building and the need to achieve one or more specific performances. The authors sustain the hypothesis that the process of challenging freedom of expression on the one hand and a technological and environmental performance on the other will intrinsically produce a pedagogical gain.

The shape concept exercise took about two weeks, and the students were asked to respond to the four major areas already established in the previous exercise: the architectural language, the structural system and materials, sustainability and ergonomics. This strategy was useful to inform the role of these different aspects visually and allowed greater control, increasing the likelihood of design success during these first steps of the form finding process (Turkienicz & Westphal, 2012). Using a storyboard strategy, the students described the main design ideas by means of images and text, which reflect the origins of the formal concept (Aroztegui, 2013). The resulting storyboard - describing the relation of chosen objects to the basic ideas of sustainability, such as mainly energy production or conservation - has led to the student’s preliminary design (Fig. 1, all future figures refer to the project from the same authors). In sequence, the students proposed transforming specific geometric concepts of the generating object, suffering mutations and evoluations in such a manner that it finally incorporates aspects of form as well as structure, but also left a appropriate degree of uncertainty in order to accept future peculiarities regarding the envelope, materials and ergonomics (Fig. 2).

2.2 Proof of Concept

The second stage consisted of the proof of concept regarding the house's performance whereby the students were asked to demonstrate required inputs, outputs and other specific performance values. Throughout the presentation of the project's energy, thermal comfort, and natural lighting performance, it was required to demonstrate the consistency between form and environmental performance, at a point when the preliminary study had been concluded. The results were obtained by means of computational simulations and aided stipulations of contributions of the photovoltaic panels and rain water collection. The proposed building assessment creates a quick preview of the concepts, such as electrical energy consumption, thermal comfort and natural lighing, based on assumed simplifications or annual, monthly, daily, and hourly data derived from a global database of weather information. By using these results the students may improve their designs (Bergman, 2012). The stipulation and simulation of environmental variables required a theoretical base on specific technologies, which - in the begining of the term – were desseminated during a series of lectures on Structural Building Systems, Photovoltaics, Passive Houses, Efficient Lighting, Environmental Comfort and Waste Water Treatment.

In more detail, the results were achieved using dynamic spreadsheets and the computation tool Autodesk Ecotect Analysis (Autodesk Inc., 2014), importing the model either from Google/Trimble SketchUp or from CAD. This tool was chosen due to its free access and ease of use, also guaranteeing quick results due to short processing times. Another alternative would be EnergyPlus (U. S. Department of Energy (2), 2014), but it use was discarded because time constraints are making it impossible to guarantee the student's necessary theoretical and practical capacitation.

The students were able to determine whether the model was receiving suitable natural lighting levels using the Daylight Factor analysis (Fig.3a). In other words, a model with satisfying results is very likely to achieve savings of artificial lighting during daytime hours. Furthermore, the analysis of the Incident Solar Radiation contribuited to the evaluation of the project's potential to produce and store solar energy consequently resulting in the capacity to heat the interior space during winter and attending the need for shade in the summer month (Fig. 3b, 3c, 3d). The thermal comfort analysis uses discomfort expressed as Degree Hours in order to evaluate and compare the projects' performance (Fig. 4).

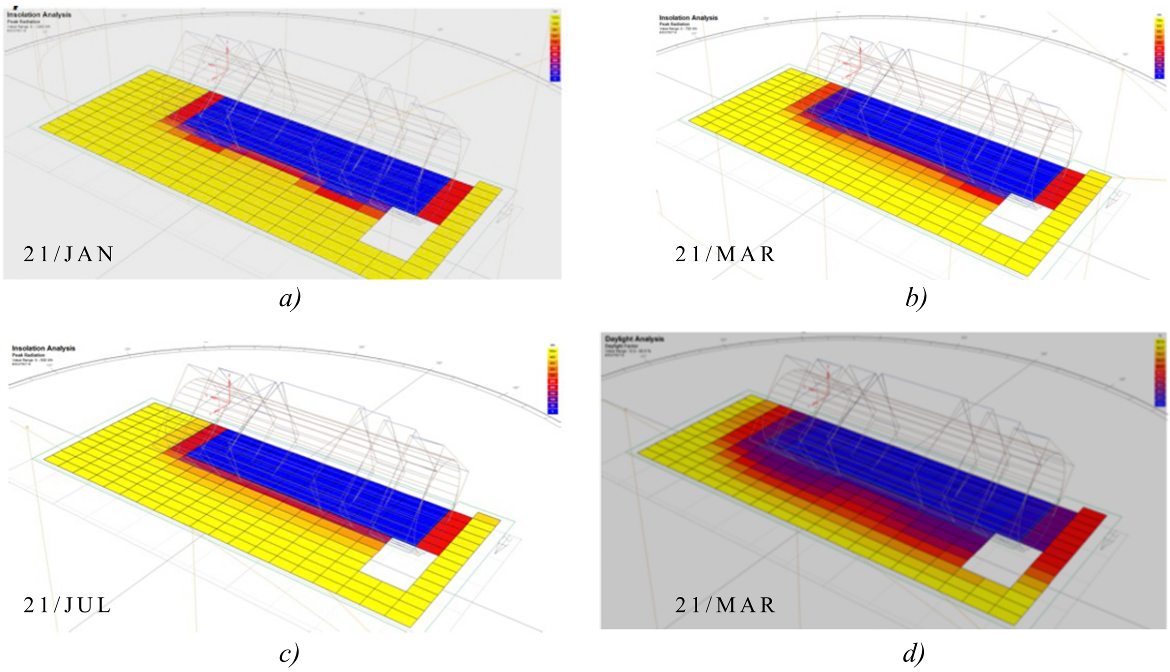

Figure 3 *Solar Anlysis: (a) daylight analysis shows daylight factors between 2 and 10% in the interior zone, (b) solar radiation analysis for 21/JAN, (c) solar radiation analysis for 21/MAR, (d) solar radiation analysis for 21/JUL.*

The energy balance evaluation should consider the entire amount of electricity consumed by appliances such as electric lighting, refrigerator, dishwasher, washing machine, and microwave oven as well as the energy produced by renewable sources such as photovoltaic panels (Fig. 5). The performance tests also involved the water balance created by the comparison between the points of consumption such as showers, washbasin, toilets, kitchen sink, dishwasher, washing machine and the water generated by the process composed of rainwater as well as gray water collection and respective treatments. In more detail, the autonomy from external fresh water sources is in most cases addressed by using stored and treated gray water for irrigation, cleaning and toilets. Indeed, the harvested and treated rainwater is reused for drinking and washing purposes.

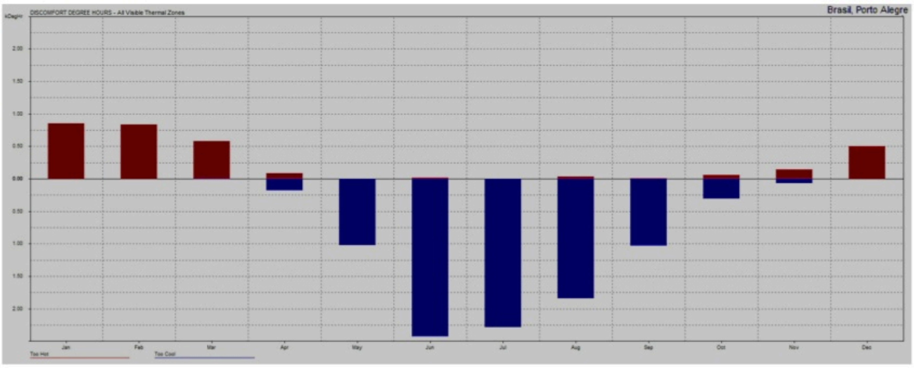

Figure 4 Annual Discomfort Degree Hours: shows a total number o 3138.3DegHrs of discomfort (too hot), 9176.6DegHrs of discomfort (too cool), totalizing an annual total of 12314.8DegHrs, thereby the design should be refined for the winter month of the southern hemisphere.

2.3 Final Technological Adjustment

In its third stage, the term project featured the refinement of the architectural design through the integration of aspects related to structure, construction and installations. This step emphasized the importance of correlating the architectural language with the technological demands. In other words, the students were encouraged to propose architectural solutions, which absorbed the technological demand (Fig 6). This phase enabled formal refinement, since at this point the student had the quantitative data needed to improve or change the qualitative aspects of his/her design. Energy consumption tables with negative results meant that energy demands had to be reduced or, alternatively, production had to be increased. As the production of energy is basically the result of the performance of the photovoltaic panels, it may be necessary to increase the efficiency of the product, optimizing the position related to the solar incidence or implementing a larger area of panels. In this final stage, the term project featured the refinement of the conceptual architectural design, which can enhance the conceptual form, but needs to additionally consider the building as it isconceived as a whole system, where the structure integrates the installations and the constructive system solves every different type of joint and/or interface between all components. For example, the structural systems as well as the sealing components may be designed as part of the solutions for HVAC, electricity and hydraulics systems (Fig. 7).

Figure 7 Technological adjustments: (a) the tube section forms the structural system of the house; (b) the final design.

3. THE EVALUATION SYSTEM AND RESULTS

The evaluation results showed that, during the first steps of the form finding process, the students obtaining above average scores for the conceptual integration of elements responsible for the environmental control presented the best solutions for the architectural and technical realization of the building envelope as well. The detailed resolution of the architectonical elements, such as photovoltaic panels, solar thermal collectors, solar protection and/or insolation, has been handled best by students who had managed to integrate these concepts into the overall idea at the beginning of the course. The same group of students would be expected to achieve the best performances. However this is not confirmed by the results at hand. Throughout the performance analysis of these student's designs, the results have no obvious correlation with either the successful integration of the concepts into the idea or their detailed solution in the architectural elaboration of the project. A typical example is the balance between solar gains for daylighting on the one hand and heat accumulation caused by the same source of energy. These aspects involve a combination of profound studies of theory and practical experience, which students typically do not present at this given academic level.

When analysing the results by standard deviation for the categories related to the architectural elaboration of the building envelope as well as the resulting performance, two main observations can be made. Firstly, the lowest deviations are found in the categories regarding the photovoltaic panels and the energy balance, respectively; these categories also present the highest average scores. Secondly, by far the greatest deviation among the categories for the building envelope was found regarding warm-water production, while for the performances most differentiated scores have been obtained for thermal comfort, which consistently presented the lowest average scores. The first fact can be explained by prior education and the project's focus in this specific criterium. An enquiry, although performed during a later semester, shows that students consider solar energy as the topic on which they have the most complete knowledge base compared to other technologies like thermal power generation or waste water re-utilization. Starting the semester with the analysis of case studies from the Solar Decathlon has predictively led to concepts and consequently technical solutions that are fit for this type of technology and have resulted in well elaborated energy generation mainly based on it. The second co-relation shows that the students either did not have sufficient prior knowledge of certain other technologies, such as warm water generation, or were not able to acquire such knowledge either from the theoretical lessons, from examples such as the analysed case studies or on their own during project development. Especially in the case of the thermal comfort the deviation must be explained by the low scores some groups obtained with wrongly executed simulations or erroneous representation and misinterpretation of the results they obtained with Autodesk Ecotect.

4. FINAL CONSIDERATIONS

In general, it may be affirmed that throughout the 14 projects turned in at the end of the term, the proposed methodology has ensured a relative homogeneity of results with respect to the pedagogical objectives outlined at the beginning of the semester. The evaluation of pedagogical procedures indicated the importance of emphasizing a constructive awareness even in the initial stages of the design process. Although the designs developed in 2013/2 reached high levels of formal exploitation (Fig.9), the projects show a difficulty in reconciling this exploitation, especially with the constructive systems employed.

In more detail, the inicial phase of the course, dedicated to the student's analysis of one project from the Solar Decathlon competition, functioned as an introduction to the methodology developed for the course. Nevertheless, the authors noted that the students did not assimilate sufficient knowledge during this stage in order to incorporate innovative solutions from the analysed projects into their own. As improvement, the authors will try to implement the use of fisical models of the analysed projects in future semesters to improve the three-dimensional understanding of the implemented solutions and consequently raise the level of detailed understanding of the system as a whole. Another desired enhancement would be additional time for the refinement of the project based on the performance results obtained. Two weeks dedicated to this revisitation of the proper project would not only sharpen the understanding of the results itself, but also strengthen the understanding of the intertwined processes of sustainability, architectural form, and employed materials.

Finally, the integration of the architectural language, the building energy consumption and other described sustainability issues, involving building systems and requirements, have both process-related and aesthetic aspects. The concern with the process of all parts of the design emphasizes that sustainability is at the core of the design process together with other design parameters such as function, structure, construction and installations. The teaching strategies used is leading the authors to develop a methodological path to design, evaluate, demonstrate and qualify the object at all design stages, from conception to installation. The exploration of architectural language during the conceptual phase and preliminary studies of the house gave the students an opportunity to bind architectural forms to the goals of environmental performance. The three-step methodology has helped students to expand their awareness of the risks of designing without attention to environmental aspects. At the same time, the manipulation of performance models throughout computational tools allowed the students to feel confident in their environmentally tested designs.

Technical and Culturally Sensitive Solutions to Foster Sustainable Housing in Southern Angola

Joana Aleixo, PhD Student *[IST/EPFL]*

Luca Pattaroni, PhD *[EPFL - Lausanne]*

Manuel Correia Guedes, PhD *[Instituto Superior Técnico]*

ABSTRACT

Studying housing solutions demands a multidisciplinary concern in order to come up with comprehensive answers able to account for physical, social and cultural needs. It is, therefore, fundamental to bring up those needs into the housing creation process.

In the City of Ondjiva, in Southern Angola, as throughout the world we can observe a lack of habitability in its slum areas, associated to the existing economic conditions. In most cases the settlement isn't provided with basic infrastructures, does not respond adequately to the climatic demands, which leads to the development of unhealthy environments. Additionally, the house in the city follows European or contemporaneous models which don't produce culturally oriented answers for the local inhabitants. As a result, the poorest housing areas are characterized by two major inadequacies: constructive and cultural.

This proposal intends to bring into the discussion the need for architectural solutions that are culturally sensitive (user-oriented), as solely technical solution appears to be detrimental to the diversity of ways of life characteristic of contemporary cities. Furthermore, it intends to alert to the need of exploring new technologies in order to turn the expertise accessible to the housing construction current actors, in a context of great poverty.

The goal of this proposal is to create an innovative IT tool, an Expert System which will integrate both results from environmental-behavior studies of a specific cultural group, and sustainable design solutions. It will be produced as a tool to help in the design of individual housing profiles and consist on the construction of a System of Relations between three pre-established group of settings, cultural, everyday life activities and architectural, in order to find a multidisciplinary response for the problematic of housing inadequacy and lack of constructive, comfortable and hygienic conditions.

INTRODUCTION

This paper is based on a research done under the PhD program in Architecture at EPFL and IST, focused on the search for alternative solutions to foster sustainable housing development in Southern Angola. The main goal of this research is to improve housing design and construction processes in slum areas, where self-building prevails; it explores the use of new technologies in order to make expertise accessible to the housing construction current actors, in a context of great poverty. The research is addressed to the case study of self-built housing in the City of Ondjiva in Southern Angola, giving special attention to the cultural aspects of the Kwanyama People (local majority group) and to the region's climatic conditions.

Author A is a PhD student at Instituto Superior Técnico, Lisbon Portugal and at École Polytecnique Féderale de Lausanne, Lausanne, Switzerland. Author B is na Assistant Professor at École Polytecnique Féderale de Lausanne, Lausanne, Switzerland. Author C is a Professor at Instituto Superior Técnico, Lisbon Portugal.

It stands on the following **premises**: *The poorest housing areas in the City of Ondjiva are characterized by two major inadequacies: cultural and constructive. It is therefore, urgent to find adequate cultural and technical solutions to foster sustainable housing construction.*

Ondjiva, as a City, was implemented in 1915 by the Portuguese military forces and it was designed and developed according to European models as well as the housing models within the City. After almost one century it can be observed that the urban areas have developed in complexity and dimension. Levels of acculturation have also increased, but despite this process of change since 1915, the existence and search for traditional housing models persisted; strong traditional traces are still present all over the city, particularly in the poorest housing areas where traditional values prevail, reflected in daily practices and in the living space. Simultaneously the housing construction in the City poorest areas lacks of sufficient habitability conditions due to the lack of construction knowhow and due to the economical conditions in which the majority of the population arrives at Ondjiva, not allowing them to hire a constructer or to have access to better construction materials.

Cultural inadequacies

There is a great body of literature on Ondjiva and the Kwanyama region which brings to the attention, among cultural, socio-economic and migration issues, facts about the construction of vernacular housing, to be considered in this work (Estermann 1961, Monteiro 1994). There is however no information on the issue of slums in the City of Ondjiva, besides the government urban plans and reports which present a general overview on the main construction and architectural characteristics in the City (Government of the Province of Cunene 2005).

In the City of Ondjiva, self-built houses correspond most of the time to two main aspects: an urgent need for shelter (built according to the scarce economic resources) and to the perception that each one has about what should be a "better house". Usually a better house corresponds to the houses of the wealthier people, houses constructed with more durable materials and following standard typologies (European models are the most followed). As a result, a self-built house in the poorest areas is generally a parallelepiped simply subdivided in the possible number of divisions (the most common are 2 or 3divisions **as shown in Figure 1**).

Figure 1 Examples of housing construction in the poorest housing areas of Ondjiva

Nevertheless, if not in terms of house form, we find a lot traditional traits within the City, especially in the exterior arrangements and in the way people inhabit both the interior and exterior spaces. For example, the internal layout of the house consists mostly on bedrooms, which for the most traditional people, are only used to sleep at night; during the day, the interior of the house is rarely used. Instead, there are other structures that are constructed in the exterior of the house to be used during the day, which replicates the traditional habits of a vernacular housing: covered structures which serve as living rooms, named Okatala (even if sometimes there is an internal one,) or external kitchens, also with special specificities, named Epata. Therefore, where the main house building (generally a family house is constituted by more than one building) tends to follow the city social patterns, annex structures are the ones often built for specific traditional proposes or activities. As such, the main building assumes a "false centrality", a symbolic and representative centrality, while the annex structures embrace the real family needs, tasks and everyday life practices, full of traditional and cultural significance. This conflict of social aspirations and customs (on one side the desire for wealthier houses, according to the contemporary society patterns and on the other side the persistence of traditional values and practices) leads to great incoherence in the self-built housing structures and spaces.

Constructive inadequacies

Along the general lack of infrastructures related to the economic conditions, most of the buildings do not respond adequately to the climatic rigorous demands, offering unhealthy environments.

The climate of the Kunene province, where the City of Ondjiva is located, is essentially of the semi-arid type, with the rainy season coinciding with the summer months (when the average temperatures are higher). The average temperatures in the region are close to the ASHRAE Comfort Standards (ASHRAE, 2005), having an annual average temperature of around 23°C. However, in terms of maximum daytime temperatures, these are often outside conventional comfort boundaries, as well as the large temperature variations between night and day, reaching amplitudes greater than 15ºC. The absolute minimum value recorded for Ondjiva is -2,3°C in June 1944 and the maximum values of 40.5°C and to 39.9°C were achieved in November 1941 and September 1964, respectively (Govern of the Kunene Province, 2005). Daytime temperatures around 30°C or more are frequent, with a drop to 10°C during the night, meaning that extreme conditions are verified, which can potentially lead to (excessive) energy consumption through the use of HVAC - unless oriented bioclimatic design strategies are applied.

In a study made under the Sure Africa project's investigation (http://www.sure-africa.org) the conventional comfort zones of ASHRAE were overlapped with the zones of influence of the various passive techniques based on research conducted by Givoni (1969). The results showed that according to its climatic characteristics, Ondjiva is under the influence of four passive cooling techniques such as day and night ventilation, thermal inertia, evaporative cooling and humidification. There is a period where heating is needed, which can be obtained in a passive way by taking advantage of solar energy, for example by orientating the building according to the sun projection or by a correct sizing of the glazed surfaces (Correia Guedes and Aleixo, 2011).

The current self-built buildings in the City usually do not present any of these characteristics. On the contrary, they commonly have no enough natural ventilation, no sufficient inertia, adequate shading or a correct solar orientation. The solar orientation is random except when it is related with traditional aspects, placing the main entrance at East. **Figure 2 show** the thermal and humidity performance of 3 different housing buildings within the city, for the period of one day; the respective buildings, among 17, were monitored with data loggers, measuring the interior and exterior temperatures and humidity values in intervals of 30 minutes, between June and July of 2013.

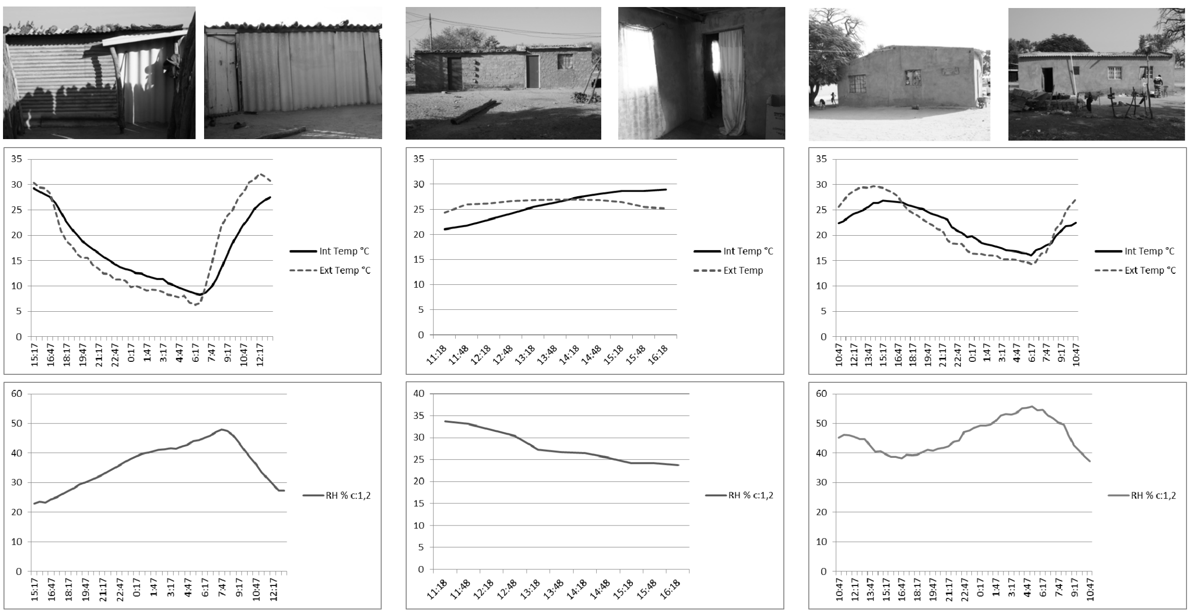

Figure 2 Temperature and Humidity monitoring of three buildings in the City of Ondjiva

These buildings represent the worst, medium and the best types of self-building construction in the City in terms of thermal comfort. The first one, **at left in Figure 2**, corresponds to an urgent need for shelter and it is composed of one room only, built with zinc boards, fibber cement boards and wood or pick to stick structures. The second one, in the midle, corresponds to a medium solution, built with handmade cement bricks and uninsulated zinc boards for the roof. The third one, at right, corresponds to an improved and phased construction, which started in 2000, with the construction of two single rooms; in 2001 a small interior kitchen and w.c. were added and in 2005 the living room and one sleeping room were built. The building materials differentiate from ruins remains (stone, bricks, etc) in 2000, handmade adobe bricks in 2001 and cement bricks in 2005, and the roof is made of simple zinc boards with no insulation. The exposed measurements correspond to the part constructed in 2005.

As shown in Figure 2 the 3 buildings have a weak thermal performance. Work made on building performances analyses for the City of Ondjiva (Correia Guedes, Aleixo and Pereira, 2011) show that some of the best practices for construction are:

1. Building optimum orientation: E-W axis orientation;
2. Minimum glazing distribution to East and West facades, 15% to 30% maximum of glazing areas in South and North facades, horizontal and vertical shading devices on East and West facades and horizontal ones on South and North facades are passive strategies which improve the building behaviour;
3. Rammed earth walls on existent buildings have better performance than the usually used concrete block without insulation;

In summary, the house construction in the city doesn't present oriented answers for either cultural (social, community and everyday activities aspects) or the buildings' comfort needs. The buildings where the largest part of the population lives in Ondjiva, particularly in suburban areas, are still very poor, with low levels of habitability; most of the times, they are buildings that respond to an urgent need for shelter, not being constructed to last and which lack of almost all the support basic infrastructures. This brings us to the next point: "what is needed?"

THE NEED FOR WHOLE AND MULTIDISCIPLINARY ANSWERS

Solely technical solutions can be detrimental to the diversity of ways of life characteristic of contemporary cities; interior confortable spaces will not be enough if they won't allow the continuity of cultural specificities. For example, the houses built recently in the City by the Government for the community do not offer proper external shaded spaces for group reunions, exterior kitchens, separated dining spaces, separated husband/wife sleeping rooms neither respond to the strong hierarchies within the family. These are specificities of traditional cultural patterns that when neglected may have serious results (Rapoport, 1969). Indeed, it is in the outside space that the most traditional activities take place and annex structures are often built by the inhabitants to meet the specificities cited above.

There is an urgent need to bring whole and multidisciplinary answers to the housing processes in the city of Ondjiva, in particular to the self-building one, instead of trying to stop those processes or change their current actors. Only by reaching the individual actors is it possible to find a global answer for the improvement of the living conditions. As we suggest, it is fundamental to relate culture to the built environment on the search for culturally oriented housing solutions; but the central problem resides on how is that relation established and in the variables that are applied in the relation process: *How to define the settings that make up culture? How to understand the world views and values standing behind what is called culture? How to understand which values should or not prevail in the future housing design? And finally, how to relate culture with technology?*

Culturally Sensitive Approaches and Technological Answers

Culture has been one of the main concerns in the study of housing since the 1960's when several authors began looking to the built environment as a result of many culture influences. Assessing culture is particulary relevant when trying to analyse and evaluate its impact, in this case, on housing.

The Environmental-Behavioural Studies (EBS) model from Amos Rapoport represents an important tool in analysing which factors influence the house form, allowing to evaluate those factors and to measure them in order to understand how the build environment (housing) responds to their inhabitant's specific needs. The EBS model from Rapoport breaks down the influence of culture, on one hand as a group of social variables that can be measured within a System of Relations, and on other hand as an expression of lifestyle and values which leads to the activities happening in a specific space. For the author, the design of one space where a certain activity will take place corresponds to the specific arrangements which need to be done for the activity to happen, paying attention at the same time at how the activity is done, the meaning of that activity for the culture and its social or ritual significance (its latent aspects) (Rapoport 1988). The goal of Rapoport's EBS model is to provide a framework for the understanding and study of the group of settings which compose the Built environment, and for the establishment of a system of relations between those settings and the latent aspects of activities, leading finally to the "housing profile" (final result).

Existing works on culturally oriented housing studies are not yet completely applied to housing design. Indeed, the existing research is more focused on housing evaluation rather than new housing conception processes (see Khattab 1993 and Sungur & Cagdas 2003). On the other hand, there are multidisciplinary approaches on housing development, but almost all of them stand in one-to-one participatory relations between the architect and the future inhabitants (UNHabitat, Diébédo Kéré). That is perhaps the most correct and productive approach but it is difficult to implement in a context of massive self-building production, at least without changing its current actors. Designing for each individual is a difficult, if not impossible, task to achieve and it is impossible to think that it would be economically viable. Therefore there is an urgent need to think on alternative solutions to improve the existing poor housing conditions in the poorest housing regions in the World; not only multidisciplinary solutions but accessible solutions and of easy application in the context of self-building housing in slums. *How, then, to come up with a multidisciplinary solution easily accessible to the self-builders in a context of poverty and architects absence? How to share the knowledge?*

HOW TO MAKE THE KNOWLEDGE ACCESSIBLE TO THE SELF-BUILDERS IN A CONTEXT OF POVERTY AND ARCHITECT'S ABSENCE?

First, in order to develop integrative and oriented design, it is fundamental to understand which procedures are more appropriate to share specific information, and how to make this information comprehensive and fully applicable (Friedman 2003; Akrich 1987). As Yona Friedman suggests, other languages than sole formal one of architecture must be found, which must be *simple* (understandable and easy to use), *significant* (direct, clarifying which consequences are implied in one decision made according to the plan described through that language) and *interpersonal* (discard form expressions that can have different meanings to different persons) (Friedman 2003).

This proposal intends to build up a similar System of Relations to the one proposed by Amos Rapoport, which will relate three pre-established group of settings, cultural, everyday life activities and architectural, in order to be able to give specific answers to the housing construction. Plus, it intends to bring the System of Relations to the future inhabitant and the future inhabitant to the System of Relations, turning it user interactive, which is possible by the creation of an Expert System, an IT tool that will embed and support the System of Relations. It is important to remember that we are working in a context of architect's absence and where the house planning procedures do not include a prevailing housing design. Therefore the search for alternative solutions is based on the following postulate: *if we can't have experts orienting everyone's house construction, we can at least try to make the expertise accessible to everyone*. It is in this sense that the Expert System is created; it shall be able to replace the expert and transmit the knowledge to its users, in a *simple, significant and interpersonal* way. The Expert System will allow simulating specific housing profiles – at the same time bio-climatically optimal and culturally sensitive – as a way to combine the advantages of a face to face participatory process and an inproved building procedure.

The development of an Expert System

"An Expert System is one in which human Expert knowledge about a specific domain is encoded in an algorithm or computer system" (Luger 2004); "the core of an Expert System is the knowledge-base, a database in which the main domain-related intelligence is encoded. Such a database is typically populated using the knowledge of one or more human Experts (…) In addition to being an informative stand-alone resource, the knowledge-base is a critical component in the Expert System" (Lee and Andersen 2009). The knowledge base will be constructed according to the available data resources, that is either heuristics either experimental, either qualitative either quantitative. It will also be based in optimization methods or algorithms for building design decisions, as the genetic algorithm (GA) (Goldberg 1989). In the proposed Expert System the user will be guided through a step-by-step process in which programmatic and constructive directives definitions are gradually decided towards the user's goals while respecting the pre-established System of Relations between cultural, activity systems and architectural variables. As stated, this system is meant to be user-interactive, flexible, and oriented to the specific case of Kwanyama People building their houses in the City.

The **concept behind the System of Relations** is the systematization of the architectural thinking process when conceiving a house for a particular user. It is fundamental to fully understand the cultural and personal context in which the user lives to better understand the needs and wills towards his future housing; this is, to be able to define the group of settings (aspects) which compose the built environment and therefore the architectural form.

The System of Relations – one of the most fundamental research question at stake - will be reflected in a decision "tree" that after inserted in the Expert System and according to the user's input, will lead to the final Housing Profile (group of culturally, architectural and personal oriented directives for the housing conception). It constitutes the Expert System's knowledge base and it is built on the principle that every aspect/variable, within the climatic and constructive, cultural and activity system's contexts, has an architectural implication. The set relations are translated into a decision tree, which is constructed by accomplishing the following steps, **as shown in Figure 3**:

Step 1 – Defining the **aspects/variables** within the Kwanyama culture; aspects of the people living in self-built houses in the City and their everyday life practises, of the construction procedures, climate and local environment (social, economic and urban);

Step 2 – Understanding which **architectural implication** can each aspect/variable have;

Step 3 – Defining the **group of aspects/variables** within each architectural implication (as the group of settings that compose the architectural form);

Step 4 - Defining which **relations** within each group of aspects will influence the architectural form;

Step 5 – Defining the **procedures** that will allow, ultimately, establishing the System of Relations.

Step 1	Step 2		Step 3	
Aspect 1	Aspect 1 →	Implication A,B,C	Implication A →	Aspect 1, 4, 5…
Aspect 2	Aspect 2 →	Implication C, D, F, G	Implication B →	Aspect 1
Aspect 3	Aspect 3 →	Implication E	Implication C →	Aspect 1, 2, 5, 8
Aspect 4	Aspect 4 →	Implication A	Implication D →	Aspect 2
Aspect 5	Aspect 5 →	Implication A, C, E	Implication E →	Aspect 3, 5
…	…	…	…	…

Step 4		Step 5
Implication A →	Aspect 1 and 4 or 5	Calculation Procedures
	Aspect 1 and 5	Analytical Procedures
	Aspect 1 or 4	Decision Procedures
	…	Probability Procedures

Figure 3 Proposed steps to create the System of Relations

These steps allow constructing the System of Relations, which takes the path of a decision tree, **as shown in Figure 4** (a); in the decision tree the departure point is the step 3 (the step 1 and 2 allow achieving to this point) in the sence that the departure point is an architectural implication (house form, division, partition, roof, material, glazing, shading, etc); to arrive to the concrete parameters of that architectural implication or form, all the aspects/variables influencing the architectural form will be inserted in the tree. According to the user's opinion the aspects/variables within the decision tree will be accepeted or refused, and only the validated ones will be related in order to establish the final directives for the construction.

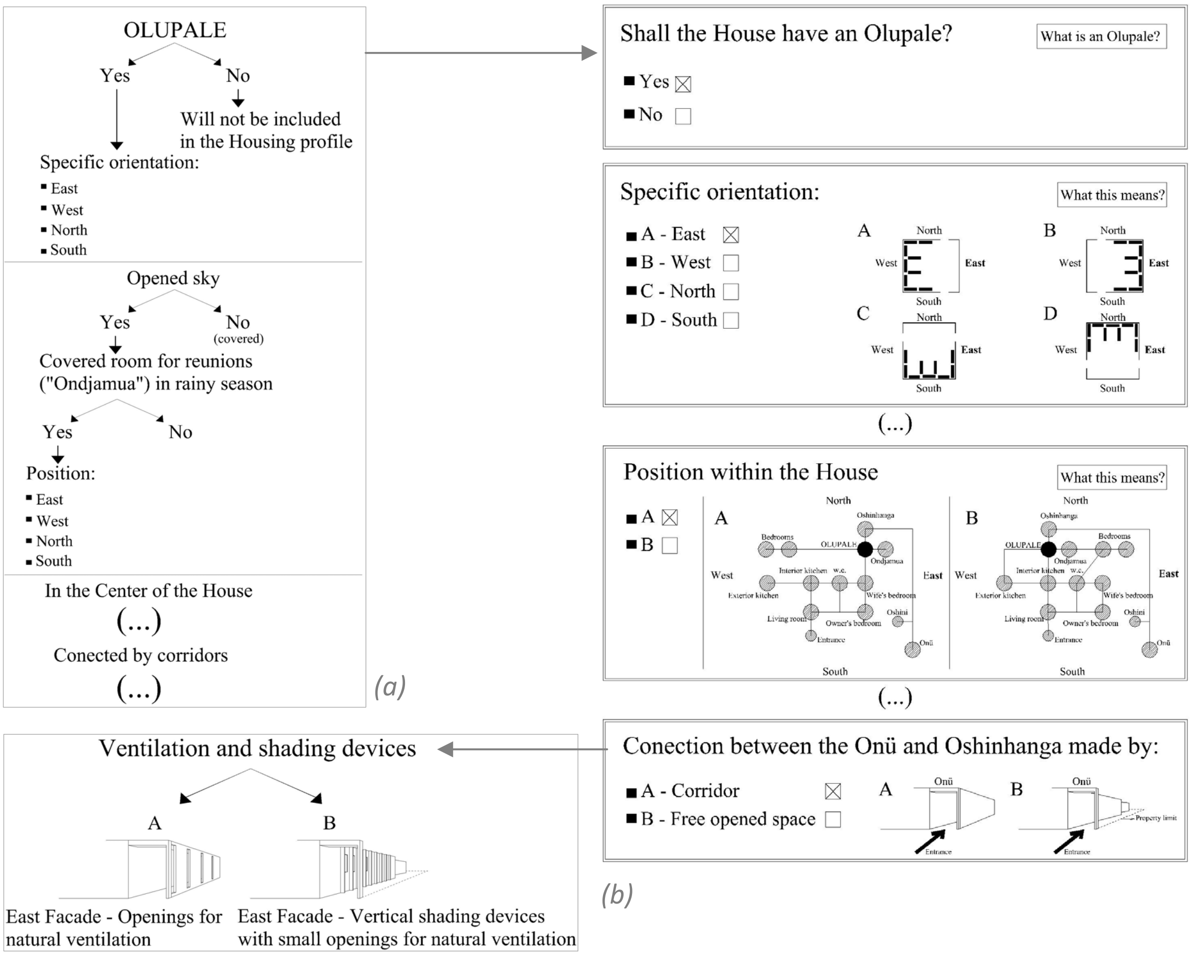

Figure 4 Part of the Decision Tree (Olupale: traditional living room) and (b) example of the Expert System layout (Onü: traditional main entrance; Oshinhanga: traditional living room for children)

The Expert System final layout will take the form of a query, **as shown in Figure 4** (b), in which the user can be an active participant in the decision of his own oriented housing profile. In order to facilitate the understanding of what is being asked in the Expert System and to help the user decide, almost all the aspects or implied decisions will be illustrated trough schematas **as shown in Figure 4** (b). The expected Expert System's output will be a group of directives for the oriented housing design. Its' expected result does not intend to reach the final design of the house and it does not intend to contribute with possible housing models because those models could later be at risk of being applied as standard models and spread without respecting the ideal of housing that responds to particular activities or particular latent aspects of those activities. It is intended, though, to help people choose among a vast group of possibilities, based on rigorous studies, and to orient them in a more sustainable construction of their house. It is made for a context of architect's absence and where the house planning procedures do not include a prevailing housing design. If one of this Expert System's outputs would be floor layouts or other technical drawings, these wouldn't, most probably, be used by the common inhabitant (he wouldn't know how). Plus, one fact supporting the feasibility of this proposal is the one of the existence of a close collaboration between the administrative housing office and the local population; almost every one desiring to build a house, goes first to the local administration to ask for a land plot. Unfortunately this relation stops here, most of the time, and the inhabitant builds the house without regard to any constructive or architectural rules. Nonetheless, the existing dialog suggests that a computer tool to be used by the poorest housing area's residents wanting to build a house would be of easy implementation at the local administrative habitat's office (since the majority of the concerning population do not have access to a personal computer).

CONCLUSION

More than a tool, the Expert System is expected to constitute a method which allows translating the environment behavioural studies concept from Amos Rapoport into direct applicable solutions for a culturally oriented housing design combining it furthermore with bioclimatic considerations. It intends therefore to constitute an alternative in the development of better living conditions in contexts of poor housing conditions, such as the ones of Ondjiva, through the application of a multidisciplinary approach. The Expert System will allow a more culturally and bioclimatic oriented self-construction and will bring new possibilities for the housing policy development, either among government institutions, NGO's or inhabitants. Therefore, the meaning of this research is in its contribution with solutions that may deliver in the future, better or more appropriate housing in slum contexts, where the self build houses lacks mainly of an oriented guiding and supervision.

ACKNOWLEDGMENTS

We thank the Government of the Province of Kunene, in Southern Angola, for the support given to collect information regarding the self-building housing in the City of Ondjiva.

ABSTRACT

This paper describes research into the development of housing in Algeria. It focuses on the history of traditional dwellings and the importance of outdoor space located inside the building: typically in the form of a courtyard. Courtyard dwellings in the city of Constantine are examined in some detail. The rapid urbanisation process taking place in Algeria in recent years together with difficulties in the planning system since colonial times has caused difficulties in responding to housing needs. The concentration of the population in smaller areas of cities has led to the need for more compact yet comfortable dwellings. The paper describes how the situation might be dealt with in the township of Jijel. A number of stakeholders are being consulted and the key results of in-depth interviews with architects are reported. The findings from the review of the existing housing areas and survey are then interpreted to make suggestions for development in the future.

Keywords: housing, urban, courtyards, design, Algeria

1. INTRODUCTION

Algeria has experienced a number of invasions and colonisations through history and this has brought new peoples and new cultures to the area with consequently new commercial and demographic inputs. These have combined with the already rich variation created by climatic regions and traditional cultures to produce a wide variety of traditional dwelling form.

In modern interpretations of architectural history, traditional architecture is often considered to be an expression of sustainability as previous generations were forced by circumstance, to build in harmony with nature and climate. Further the products were matched to cultural and social values in a much more linked way than generally occurs in the present day (Makani and Talebi, 2011). As a result traditional settlements are often considered a source of sustainable design principles because they were built using locally available materials, and with respect to thermal comfort and cultural needs of the local community (Bouchair and Dupagne, 2003).

An interesting facet of many traditional housing designs was the attempt to have some kind of outdoor space indoors; the most successful exemplar of which is the courtyard house. Courtyard houses can have many beneficial attributes – in cultural terms and also in providing the means to reduce discomfort associated with climate.

In modern dwellings there is often an attempt to bring together elements of tradition together with modern needs and also to match to the needs or urbanisation. In rapid urbanisation it is frequently the need to produce smaller and more densely packed accommodation and in such circumstances the ability to create any kind of courtyard environment is severely limited. One way of creating some kind of

outdoor-indoor space is through the provision of individual balconies. Balconies can be left open or can be enclosed.

This paper consists of three main components: firstly examples of traditionally designed dwellings which have been researched are described and evaluated; secondly particular examples of the courtyard house are examined in more detail; and thirdly, the attitudes of architects to sustainability and the ability of current urban and housing design policies to meet needs is reported following interviews.

2. TRADITIONAL DWELLING TYPES

Examples of older style traditional houses in Algeria according to Benmatti (1982) can often be divided into three categories: courtyard houses in the towns of north of the country which can be seen in the medina of Constantine for example; housing to be found in the rural and semi-urban areas of the North (this form of housing is less homogeneous than the first category and includes the example of Kabylia); and a third category associated with housing settlements in the South; examples being M'zab, Souf and Hoggar.

It is interesting to note in the following descriptions how the old styles of dwelling accommodated social and cultural needs whilst also dealing with the excesses of the climate. Some dwellings had only private interior space; some had both private and more public interior space; and in some cases the means of achieving all requirements was the use of a courtyard.

2.1 The Kabylia House

The Kabylia Berber villages are situated in the summit, slopes of mountains or in high plateaus where a dense population live from land exploitation. Topography and climate are the factors that determine spatial structure of the village, streets and alleys which follow the geographic configuration of the site. The urban fabric is often constrained by a circular road around the summits of hills, and the houses or 'Axxam' are organised along radiants or alleys that are perpendicular to the circular road. The dwellings are often grouped and link to each other to form a larger family house.

The family house shelters the whole extended family, with the overall dwelling extended by the construction of new houses sometimes in the courtyards of the parent's house. In these traditional forms where space is not limited in the same way as in modern development, two or three generations may live together and form a sub-quarter (Toubal and Dahli, 2009).

In such rudimentary houses the family, its animals, its furniture, artifacts, equipment and products all come together (Maunier, 1926). Humans and animals are juxtaposed with minimal vertical or horizontal separation. The dwelling typically had three different spaces: a high living room for people with a fireplace, a low stable area for animals and water storage, and a shed for faring equipment and crops. The rooms are used by both male and female as the men typically spend the whole day outside working on the land and only come to the house to eat and sleep. The relationship between public and private space is not well determined in the plan as the house is effectively considered as a private place.

In Kabylia houses, high humidities can be found in spaces and activities related to water such as the kitchen and bathrooms. The Brasier or 'Kanun' occupied the driest places (Loeckx, 1998). The courtyard in the kabylia house is located exterior to the house where traditional summer activities such as pottery making are performed.

The house has a rectangular from and the dimensions are typically: exterior 7 to 7.5m length and approximately 5m wide with wall-height of about 3.5m walls. The dimension can vary depending on the needs of families and the wealth or otherwise of the household. The external walls of dwellings are thick and are normally constructed without windows and thus permit protection of the interior house from cold in winter and heat in summer; the only opening is the door. The walls are constructed from local stone and the roofs have two slopes and generally use roman tiles or clay. The structural frame is based on wooden Ash beams and olive branches, and is supported by its low side walls (Maunier, 1926).

2.2 Soufi House

The traditional houses of Oued Souf are known as Soufi Houses. The Soufis or the inhabitants of Oued Souf were originally from Yemen; looking for water and better climatic living conditions, they crossed Egypt and Tunisia to settle in Oued Souf a city in the Algerian Sahara which borders Tunisia and Libya. The city is 620 km southeast of the capital Algiers. The city is located within the Oriental Grand

Erg (Great East Sand Sea).

Oued Souf is known as the ‘city of a thousand and one domes’ for its particular architecture characterised by the uniformity of styles using cupolas, domes and vaults. The old city is situated in the city centre and surrounded by three main roads, which separate the traditional urban fabric from the new town. The old city also exhibits a traditional architecture showing a compact urban structure which is characterised by a dense network of narrow twisting alleys, different in width and direction providing shaded movement between neighbourhoods (Bourbia and Awbi, 2004).

The houses are arranged around a central courtyard covered by palms branches. They are constructed by using locally available materials particularly the desert rose, stones and plaster. The original traditional dwelling of Oued Souf is called Haouch and designated to house extended families. The house is surrounded by its external thick windowless walls and attached to three other houses in order to provide a minimum exposure to solar radiation. The walls are constructed making use of local materials such as ‘gypse’ which helps to ameliorate thermal discomfort in summer by absorbing the heat during the day and releasing it at night. Also, as sand does not store much heat due to the air between its particles. It cools down quickly after sunset and may even generate morning fog in desert conditions.

The thermal performance of ‘isothermal’ flat roofs can be improved by adding thick layers of earth. In the case when the roof is a dome (the area of a half sphere is three times that of a flat terrace), it will receive relatively much less solar radiation. Therefore, it warms more slowly than a flat terrace (Fezzai et al, 2012).

The traditional house of Oued Souf comprises a semi-public transitional space ‘skiffa’ which provides privacy for the courtyard from external strangers. The skiffa is often endowed by ‘khamsa’: a traditional way to protect the house from bad-eyes of other people. The doorstep/doorway signifies the separation between the indoors and outdoors. Also, the house includes a kitchen, a cellar or ‘khabia’ and a number of rooms ‘ghorfa’ or ‘ damsa’; if the ceiling has a form of a vault, the rooms will gradually grouped together in order to satisfy the increased needs of the households.

In the North and South parts of the house, two covered spaces called ‘sabat’ open onto the courtyard. The North Sabat permits a maximum exposition to solar radiations in winter while the South Sabat and an excavated underground area provide the protection from heat in hot seasons (Nabila, 2007).

2.3 Hoggar Dwelling

The Touareg are the people who live in Hoggar; their origin is a mixture of Sudanese, Berber and Arabic. The Touareg are a group of tribes who live in the high mountains of Hoggar in the extreme south of the Algerian Sahara (Benmatti, 1982). The region of Hoggar is the highest land region in the Sahara where many summits exceed 2500m. Despite the southerly location, the region is relatively favoured in terms of climate, and in comparison to other parts of the desert it is less hot and experiences higher rainfall.

The Touareg live in tents or in small buildings called ‘zeriba’. The tents are relatively primitive and consist of a wide leather velum envelope formed by assembling tanned goat or sheep skins painted in red and sewn together. This roof is supported by a tall wooden column in the centre and generally three other columns shorter than the first: one in the middle of the open side of the tent, the two others in the two extremities from that point. Despite its primitive form, the tent can be closed at night almost completely which can protect the inhabitants from the cold nights of winter. One half of the tent is reserved for male use (storage of clothes, saddle and weapons); the other part is occupied by the woman (clothes, personal items, and kitchenware); however the two parts of the tent are not separated by any physical barrier (Demoulin, 1928).

The Zeriba is a small hut representing an intermediate stage between the nomads’ tent and more modern forms of house. It is made of stones and covered by palm leaves. The zeriba has generally a cubic form approximately 2.5 m square in plan but sometimes with a conical roof (Pandolfi, 1994).

2.4 Traditional Courtyard Houses

Courtyard housing is a universal type of habitat and it is not unique to the Arab world or to Algeria. It is widespread in diverse regions in different geographical locations, climates, societies and cultures: several civilisations have used it as the main design component of housing such as the Assyrians, Persians, Greeks, Romans, Byzantines and more recently found in Islamic architecture. However, although courtyard housing was a key feature of traditional design in many parts of the world, there are significant differences of function and importance relating to the function of the interior courtyard in the Islamic region.

The importance of courtyards has increased under the influence of the Islamic religion and subsequently Arabic architecture took this to form a specific room/space characteristic in plan, in form and in decoration. In this, the courtyard became one of the main architectural features of Arabic houses and gave opportunity to develop a variety of associated features: loggias, galleries, high level openings, oriels and elaborate sun-shade ornamentation (Edwards et al, 2004).

The study will focus on the medina of Constantine as one of the oldest medinas in Algeria and in which fine examples of traditional forms of Courtyard Houses are to be found.

3. THE MEDINA OF CONSTANTINE

Constantine is one of the oldest cities of Algeria which dates from 3000 BC. It is situated in the centre of the North East of the country. The city was a base of the Phoenicians, Romans, Vandals, Arabs, Ottomans and finally the French. The medina of Constantine is classified as of national heritage significance. The urban fabric of the medina is extremely dense and the network of streets and routes in the medina follows directly the morphology of the site. Unlike the streets and boulevards of occidental countries, the layout of roads has an organic plan and has no regular geometric form.

An analysis of the plan of the medina shows that the urban fabric has two different urban forms: a central area of souks (markets) which is exclusively related to commerce and culture; and a private residential area. The division of these areas is explained by the principle of separation between public (commercial) and private (residential) zones.

The traditional quarter of Souika is situated in the South East of the Medina. It still retains the major part of its original urban structure. The plan of Souika is composed of a homogenous irregular urban fabric. The residential clusters form small neighbourhood units within which basic neighbourhood facilities were provided such as a bakery, public baths, mosque and a school. The clusters are formed by a maze of roads with a spatial hierarchy from winding alleyways ending by cul-de-sac which maintain the public/private relationship and separation.

Streets in residential areas are either partially covered by cantilevered volumes *sabat* or totally by additional living spaces. Overall the hierarchy of streets is as follows:

1. A commercial axis as a public street.
2. Secondary roads as semi-public streets.
3. Alleyways and small streets/cul-de-sacs as private roads.

The difference between the main commercial axis and the private cul-de-sacs is one of the important characteristics of the residential urban fabric of the Arab-Islamic medina. This variation allows the separation between the private domain of housing and the public areas in order to provide privacy of houses on the urban scale. See figure 1 for an image of a typical house in Constantine.

Figure 1 Traditional house in the City of Constantine, Algeria

4. SPATIAL ORGANISATION OF THE COURTYARD HOUSE

Traditional houses in the medina of Constantine have a simple irregular geometric form consisting of two or three-storey structures surrounded by external windowless walls and organised around the courtyard. The houses are in most cases provided with pitched roofs inclined to the patio/courtyard area. The plans of the houses are generally similar in their basic characteristics but may vary in detail, and spatial organisation and the hierarchy of spaces in the houses are very similar.

Courtyard houses of Constantine are generally found in three forms:

- Houses with columns and arches which indicate occupancy by more affluent families.
- House with large pillars, columns and lintels, which represent the more generally found dwellings occupied by intermediate households.
- The third form is similar to the second but is differentiated by the elevation of its patio from the floor to allow the use of the ground floor as a store area. This type of house is generally located in more commercial street areas.

Generally however there is no social or spatial segregation between poor and rich families and both live side by side with each other, the only signs of difference being the height of the house and the decoration of the external doors. In all cases the courtyard receives and distributes sunlight and fresh air to the other parts of the house.

The courtyard also serves as the focus for the preparation of food, and as a laundry, children's play and outdoor living space. It also acts as a circulation space surrounded by alleyways and arched galleries which are designed to avoid any direct visual intrusion (from the semi public spaces into the private central space of the house). Further it provides a covered transitional space between the rooms and the open part of the court.

The courtyards of vernacular dwellings in Constantine have a regular form: square or rectangular. Their length is varies between 8-10m, whilst their depth is between 2-3m, possibly because of the limit of available cross-beam length.

Figure 2 Typical layout of a courtyard house in the City of Constantine, Algeria (ground floor left, first floor right) Key: 1 = Public (Bit, skiffa); 2 = Semi public (Services); 3 = Private (Female and family living, or bedroom; 4 = Open space (Courtyard); 5 = Transitional spaces (Riwak).

The rooms generally located at its two extremities are elevated doukana (storage places). The central area of the room (Kbu) is opposite to the door and is balanced by two lateral sitting bay areas. The house is accessed through the skiffa, a small angled space which connects the public (exterior), semi-public and private spaces of the house (Barkat, 2006). The skiffa is also the reception area for visitors, particularly men who are not allowed to enter into the house. This place is connected directly to a reception room which is the most decorated room in the house and designated to receive male guests. Figure 2 shows the generalised form of the courtyard house set on two storeys.

5. THE PROVINCE AND CITY OF JIJEL

The Province of Jijel is located in the north east of Algeria and until 1974 it was a sub-prefecture of the Province of Constantine. It is bordered by the Mediterranean Sea to the North with a coastline of 120 kilometres, and the Provinces of Skikda in the East, Bejaia in the West, and of Setif and Mila in the South. It is divided into 28 communes and 18 sub-prefectures (Dairas) and has a total area of approximately 2400 km^2 of which 82% is mountains; it has an estimated population of 650,000, most of whom live in the North part of the Province. The actual City of Jijel has an estimated population of 134,000 inhabitants and occupies just 62 km^2 (2.6%) of the land area of the province, and this results on a high density of population of 2,140/km^2 (when the average density is just 264 persons/km^2 (Wilaya de Jijel, 2013).

Due to its strategic location, Jijel has been an attractive destination for colonists since the pre-Roman times. The city was prosperous in Phoenician, Carthaginian, Roman, Byzantine, and Arabic times. Following a large earthquake in 1856, the reconstruction of the city took place under the French occupation resulting in a new city designed by Scheslat in 1861. The city was built in an orthogonal plan focused around the military garrison 'the citadel'. The plan was similar to European cities with a triangular form constrained by the terrain form and also by the layout of ramparts, the rules of fortification, and the location of the gates into the city. According to the principles of Haussmann's urbanism, this plan included the key elements of urban fabric: the regularity of pathways, the alignment of the road structure, and the important role of public areas and squares.

The distribution of the population of showed a concentration of colonists in the North part of the triangle, close to the citadel, the Sea and around the already existing facilities. The native population was grouped in the South West part of the city and occupied a very dense area with very tight access from narrow streets. In 1885, the port was rebuilt and later the Eastern area became an expansion area for the colonists who built housing developments with beautiful villas facing the beach. On the local Arab side, informal settlements spread parallel and outside the triangle and created two new quarters: la Pepeniere and the Faubourg (Safrai, 2008).

After Algerian independence, Jijel witnessed an increase in population arising from a rural exodus towards the city. However, no spatial expansion was planned and little organized construction took place. This resulted in the densification of indigenous quarters and the appearance of other new spontaneous quarters: village Mustapha, la Crete, etc.

From 1974, with the nomination of Jijel to the status of provincial town and the implementation of a special development programme, there has been a considerable rise of population (the population has multiplied by 3 times in a period of 20 years, from between 1977 and 1998.

6. HOUSING POLICY AND HOUSING DEVELOPMENT IN JIJEL

Since the 1970s there has been a very sharp increase in demand for housing, particularly social housing. In this period the city initially grew haphazardly by juxtaposition of urban entities in particular informal housing. The urbanisation of the city occurred rapidly and without much detailed forward thinking on urban development in both medium and longer terms. This has impacted on the fragile balance between the urban system inherited from the colonial period and created morphological and functional failures that make urban management rather complex (Safrai, 2008).

From 1985, the increasing housing crisis and the emergence of informal settlements lead to the launch of a major public housing program and the creation of three new zones of urban habitat 'Zone d'Habitat Urbaine Nouvelle', each of which have been designed to accommodate 50,000 inhabitants (Hallal, 2007). These Zones were well intentioned; however their implementation has been less satisfactory because of the emergence of informal settlements. This situation was aggravated particularly in the period between 1990-2000 due to the civil war, the resulting insecurity, and the degradation of living conditions in rural villages and mountains. Urban and architectural decisions in Algeria and particularly in Jijel have sometimes been made according to political and personal evaluations which are sometimes more powerful than urban planning instruments, and this can have significant adverse impacts.

One of the key design features which is seen in the high density development to meet urgent social needs in Jijel has been the lack of development with regard to traditional design. This has led to multi-storey apartment blocks which have forms of outdoor-indoor spaces – balconies etc, but without the attributes understood and liked by the indigenous population, see for example Figure 3.

Figure 3: Example of ‘closed’ balconies

7. SURVEY OF BUILDING PROFESSIONALS

The research project, of which this paper reports a part, is involved in integrating the views of stakeholders into the design and construction process in a much more influential way. However in order to do this, existing knowledge and attitudes must be known. A number of detailed interviews have been carried out with stakeholders, and the results of the first phase of these, with an influential group of architects and other professionals is reported here.

The study was carried out with twenty-one architects and engineers working in either private bureau or public administrations. The aim of this questionnaire was to assess the knowledge of architects in Algeria in terms of sustainability which can affect the quality of design and the sustainability of the built environment. It also sought views and understanding on differences between traditional and modern design of dwellings.

- On the question concerning sustainable development objectives: 16 professionals answered that they have an idea of the objectives and on what makes a building sustainable; however, only 3 out of 21 gave a suitably detailed definition and the others just related the subject to energy consumption. In addition, 17 out of 21 think that the Algerian Government is not making sufficient effort to raise awareness amongst public and professionals on the topic of sustainability.
- In relation to comparisons between modern apartments and traditional courtyard houses in terms of sustainability, 14 respondents out of 21 preferred the traditional house and they argued that the traditional design respected the lifestyle of local inhabitants. Also, they stated that the courtyard provides more natural light and better ventilation to the dwelling.
- A majority of interviewees (14 out of 21) also agreed that traditional architecture satisfied the needs of the local population in terms of space, while only 7 out of 21 thought that modern design and construction met the needs of the inhabitants. 13 out of 21 interviewees claimed that traditional design met the needs of local population in terms of comfort. However, only 4 out 21 agreed that traditional design respected urban level regulations in Algeria. Some of the interviewees think that is because the regulations were only devised some time after traditional design had evolved.
- All the interviewees agreed that it was important to consider the opinion of future inhabitants in the design of new houses.
- It was clear that the majority of professionals do not have sufficient understanding of the subject of sustainable development which affects the quality of the built environment.
- The vast majority (20 out of 21) of the architects interviewed thought that the quality and impact of urbanism and the built environment in Algeria is poor and lacks respect of regulations.

- Some of the interviewees suggested that the design of future housing projects should fulfill the ‘real needs’ of households. They also believed that future design should consider the climatic and environmental factors of the region. Moreover, they thought that the Algerian government should improve the quality of construction in terms of space, comfort and aesthetics.

8. CONCLUSIONS

Vernacular houses in Algeria have varied according to different climatic and geographical regions. Houses design, the use of local building materials and construction system were adopted for each region separately in order to cope with different environmental factors and resource availability. Thus each type fulfilled social needs and society values and traditions in different ways.

However, it is not possible simply to use the systems and practices from previous generations but there is need to study and learn from their experiences and the sustainable systems they introduced (Eiraji and Nambar, 2011) but also to adapt. Human behaviour and culture should also be considered in modern housing design (Vaziritabar, 1990) and future cities should be created by learning from historic and traditional cities: conserving cultural heritage and promoting sustainable development in order to suit contemporary needs.

Urban policies which lead to new housing development need to take into account the older traditional forms but in new ways such as to introduce new forms that can replace the older courtyard form seen so successfully used in Constantine. New housing must also be sustainable and therefore new policies and actions must be informed by current stakeholder views but also seek to address and modify those stakeholders’ opinions. The results of the interviews indicate areas which require attention and can be developed for more sophisticated analysis. This research ultimately aims to combine sustainability potential in traditional architecture with modern technologies and occupant needs to create new sustainable cities that suit present and future needs of the inhabitants.

[1]nesrine.merzougui@gmail.com / [2]imane_chabane@yahoo.fr

ABSTRACT

The city of Algiers comprises eight museums, more than half of them are reused buildings. In this paper, we are interested in the museographic lighting requirements in reused buildings that haven't been initially designed for expographic purpose. The conversion of buildings into museums may have some constraints. Natural light is an important constraint whose modeling depends on formal, structural and spatial characteristics of the building. And supplying with artificial lighting depends largely on it, thereby having direct repercussions on energy consumption. Conversion of historic buildings, in itself exhibition subjects, can also reduce adaptive space possibilities to museographic lighting requirements. This paper is the synthesis of a master preliminary study where we attempt to assess the exhibition's lighting quality in three reused buildings, based on blueprints (metric supports), the author's observation and photographic supports. This preliminary assessment is aimed to evaluate the case studies through literature recommendations of "accent" and "ambient" lightings in exhibition spaces. Despite the constraints related to the conversion of a building into a museum and the importance of lighting design in expographic quality, it may be possible to ensure a lighting quality by adapting the collection types to the space opportunities especially related to natural light. The heavy architectural structures present more constraints than light architectural structures, limiting exposition to permanent collections, especially 3D artworks with consequent dimensions that are the best recommended with natural lateral lighting. Oppositely, the light architectural structures induce flexible and big spaces that seem to be the best adapted to temporary collections especially when offering natural zenithal lighting for "ambient" requirements.

INTRODUCTION

Exhibitions, representing places of themes, interaction, communication and entertainment, are available in a wide range of types, varying according to the theme, content, temporality, scenography and the space housing the exhibition. Museums, being the warehouse of our tangible cultural heritage, represent the largest exhibition venues [1]. Museum culture in Algiers tends to be developed through various activities that take place in the institutions of the capital, and whose number is increasing. This has in part led to the conversion of a number of buildings into museums to host this kind of cultural events. The quality of a museum exhibition is conditioned by a number of requirements related to visitors comfort, artworks conservation, and to the exhibition space itself. It is through these requirements that "lighting" is raised as a predominant factor [2]. In this work, the interest is focused on expographic lighting, especially on two of its components, which are "ambient" and "accent" lighting. The third being the "orientation" lighting that has a very little influence on modeling space and appearance of the exhibited artworks. The expographic lighting is provided by the combination of natural and artificial lighting that depends on some parameters: temporality (with exhibits that may be permanent or temporary), the type of collections on display (2D or 3D objects), and the space housing the exhibition. If the natural lighting is yet a challenge that has to be met in the first phases of the design process, because its management and modeling depend entirely on the formal, structural and spatial characteristics of the building~~,~~ that influence the distribution of illuminance, luminance ratios, and the perception of light, what to say about the building converted to host a museal exhibition~~,~~ that involves considerable constraints, inducing an important supply of artificial lighting with considerable energy consumption [3, 4]. In this paper, we attempt to raise the qualitative aspect of museum lighting through some recommendations issued from a preliminary assessment of three case studies. These recommendations could help the architect to integrate lighting feature in upstream of his reflection in the design of a museum or conversion of a building into a museum.

MUSEOGRAPHIC LIGHTING REQUIREMENTS

Combined lighting

The perception of the exhibition, the visitor intuitive orientation and quality of environments are a central concern in a museum space. A suitable level of lighting must meet the requirements of the conservation works and facilitate the adaptation of visitors to the area, while distinguishing each space from another, etc [5]. The museum lighting is defined as an underlying factor in exhibition quality, and is declined in different types, but the focus in this paper is on its role of expression element through expographic lighting, as “ambient”, and “accent” lighting. “Accent” lighting helps to highlight the exhibits and the architecture, and to emphasize their various components and characteristics. This induces the creation of a hierarchy in perception, depending where attention must be captured [6, 7]. “Accent” lighting is designed for numerous purposes such as differentiating objects or artwork through various levels of illumination, or more precisely to model sculptures, etc [7, 8]. While “Ambient” lighting is generally a diffused lighting designed primarily to show the proportions in a space and the limits of a room. It provides the space a general brightness that facilitates the observation of displayed artworks, as well as showcasing the space itself [2]. So, we can admit that museum lighting is a secondary language, meeting the criteria of a semiotic system as its other elements, resulting in the interaction between space, object and visitor [9]. With all these considerations, the expographic lighting depends largely on the exhibition theme and the expected impression and emotion to provoke. Concerning the conversion of a “historic” building into a museum, the expography has to embrace the space, avoiding any additional structure that might affect the building itself as an authentic “heritage”. Its design is related to the exhibition temporality, the exhibits type (2D or 3D) and the existing natural lighting devices~~.~~

Natural lighting

Advances in artificial lighting tend to reduce the importance of natural lighting in architecture, and so in the exhibition spaces. But improving the architectural experience, ensuring greater satisfaction through the artwork appreciation, connecting the visitor with the outside, ensuring a positive psychological impact, and reducing the energy consumption; are all_reasons that encourage the integration of natural light in exhibition spaces [3, 10, 11, 12, 13]. Natural light is assured by different device typologies~~,~~ with various characteristics and effects, such as lateral lighting device, zenithal lighting device and polar oriented skylight [8]. Concerning the “ambient” expographic light, configuration and characteristics of the space play an important role, because the space’s height and surface, the proportions of openings, and so on, determine its ambience. Soft diffused light is generally considered as a leading “ambient” lighting element. For the “accent” lighting, zenithal and polar oriented devices are the most recommended for lighting two-dimensional subjects (2D) and present the best compromise for daylighting a flexible space hosting temporary exhibitions, preventing direct sunlight from penetration and overcoming the reflection that causes glare~~s~~. While the lateral lighting device is the most constraining for 2D artworks and particularly for temporary exhibitions, it is better suited to permanent exhibitions composed of 3D objects due to the shading patterns generated by the luminous flux.

In the following table are summarized the literature recommendations about expographic natural lighting devices that we classified into four ascendant degrees of quality: “less recommended”, “just recommended”, “well recommended” and “highly recommended”. [Tab.1]

Table 1. Natural expographic lighting recommendations

		Natural lighting		
		Lateral 	**Zenithal (skylight/overhead)** 	**Polar Oriented skylight** Ambient		Just Recommended	Highly Recommended	Well Recommended
Accent	**2D**	Less Rec.	Just Rec.	Highly Rec.
	3D	Highly Rec.	Well Rec.	Well Rec.

Rec. = Recommanded

The openings type plays an important role in the exploitation of exhibition space; so it is recommended to optimize the exhibition surface by minimizing the openings surface. A well-designed natural lighting strategy could direct visual accent to the display without glare surface at modest levels of lighting. In this context, the electrical lighting loads can be reduced and compensated by the natural light, instead of an increase in competition with excess of clarity [8]. The objectives of natural lighting exploitation in the exhibition spaces consist~~s~~ in maximizing the light source by using its features and eliminating its defects and drawbacks. This is done by considering parameters and requirements related to the space, the exhibits sensitivity, as well as the visitors’ comfort [9, 11]. And so, natural lighting should be considered before each exhibition program for both conservation and exhibition requirements. Its expertise generally supported by detailed graphics on devices and openings, should be perfected by an experimental computer modeling showing the lighting comportment [2, 11].

Artificial lighting

Unlike natural lighting, the peculiarities of artificial lighting are precision in controlling the direction and amount of light used, as well as the constancy (regularity) [8]. The exhibition spaces are therefore not subject to seasonal or diurnal variations, contrary to natural light, but characterized by stability and adapted control, more suitable to the standards of artworks conservation. For the temporary exhibitions characterized by a short time visit in a museum, the flexible lighting is the most recommended, which only the artificial lighting could offer, through focused rail systems~~,~~ rotary and swivel spots, etc. [4]. Artificial source typologies are classified according to their distribution of light, and there are three main types. Firstly, the “direct light” which can be diffused, focused or framed. The “direct diffused light” gives the background a significant importance by uniting it to the exhibit, while a “direct focused lighting” narrows it. “The direct framed lighting” decontextualizes subjects through the contrast it creates~~,~~ and therefore allows the reduction of the illumination. Secondly, the “Indirect lighting” and finally the “direct/indirect lighting”. [4]. [Tab. 2]

Table 2. Artifical expographic lighting recommendations

		Artificial lighting				
		Direct				
		Diffused 	**Focused** 	**Framed** 	**Indirect** 	**Direct/ Indirect**
Ambient		Highly Rec.	Well Rec.[1]/ Less Rec.[2]	Highly Rec.[1]	Highly Rec.	Highly Rec.
Accent	**2D**	Just Rec.	Highly Rec.	Highly Rec.	Less Rec.	Just rec
	3D	Less Rec.	Highly Rec.	Highly Rec.	Less Rec.	Just Rec

Rec. = Recommanded / [1] For dramatic ambiences / [2] For soft ambiences

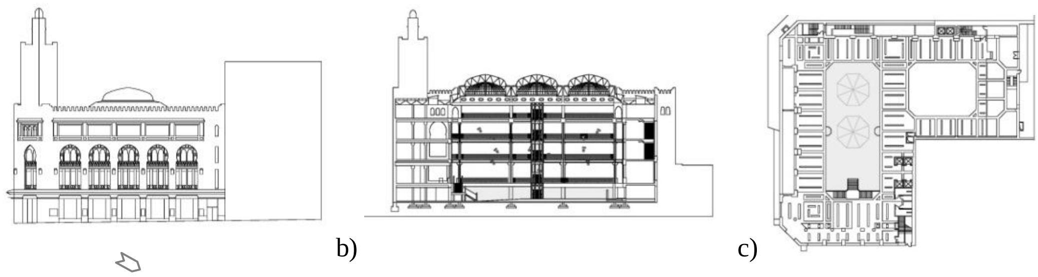
One of the main concerns of artificial lighting is energy consumption. Each project must have accurate energy balance and where possible, a comparison with the previous installation. In addition to this assessment, it is recommended to use low-consumption lamps, such as LED or compact fluorescent lamps [14]. The use of motion sensor or timer which could improve the conditions of artworks conservation is also recommended for energy economy [14]. In theoretical view, natural light should be considered as the main source of expographic lighting and artificial lighting should be considered as a complement, to bear deficits or to meet the conditions of conservation works. Even if all the criteria cited above, are difficult to combine in a museum, they must be carefully stated and considered for best expographic lighting quality [2].

METHODOLOGY

Case studies

The Museum of Modern Art of Algiers

The museum of modern and contemporary art in Algiers, called MAMA (Musée d'Art Moderne d'Alger), was inaugurated in 2008. It is the first major commercial structure devoted to the cultural sector and the first conversion operation of an old colonial monument of such importance (Fig. 1a). The museum is currently entirely devoted to temporary exhibitions and hosts 2D and 3D artworks. The building is constructed on five floors, including a basement arranged as a Central Exhibition space (atrium) and the exhibition galleries are arranged around the atrium on the different floors (Fig. 1b,c). With a natural light structure, it has three glassed domes, surrounded by small skylights, shaped like stars (Fig. 1c). A staircase initially centered in the atrium has been removed during the building conversion to offer the museum more flexibility in terms of planning.

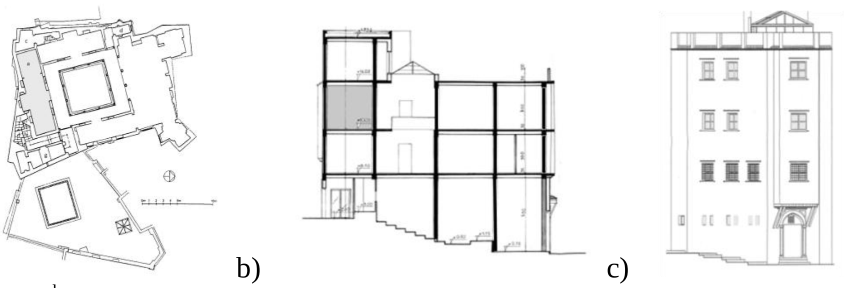


a) b) c)

Figure 1: (a) Elevation (b) Section (c) 1st floor plan.

The national Museum of Folk Arts and Traditions

The historic Palace where are kept the ethnographic collections of the Museum of Arts and Popular Traditions was built in 1570 by the Ottomans. Located in the old city, it became a museum of popular arts and traditions in 1961 after the acquisition of a permanent collection that includes around two-thousand objects related to crafts and other popular arts, which are predominantly three-dimensional. The museum itself is an exhibit, regarding the importance of its history and architecture. The exhibition entity consists of four levels with floors built around a patio and equipped with lateral openings (Fig.2 a, b, c). The whole building occupies an area of 595 sqm, and has been constructed by a rigid structure with masonry walls. The museum hosts its permanent exhibition, as well as temporary or itinerary ones.



a) b) c)

Figure 2: (a) 2nd foor plan (b) Section (c) Elevation.

The National Museum of Antiquities

The National Museum of Antiquities is the oldest museum in Algeria and Africa, inaugurated in 1896. After several displacements of the collections, the conversion of the first normal school of teachers into a museum permitted to fix these collections. The museum currently hosts historical and archeological pieces reflecting the history of Algeria and the Maghreb for two thousand years, with a collection of sculptures, ceramics, lamps, Roman pottery… which are mostly three-dimensional objects, through permanent and temporary exhibitions. The building, with a rigid structure of masonry walls, has several spaces distributed in the ground floor and arranged around a courtyard (Fig.3 a, b). It has side openings with a skylight in the dome (temporary exhibitions space) (fig.3 c).

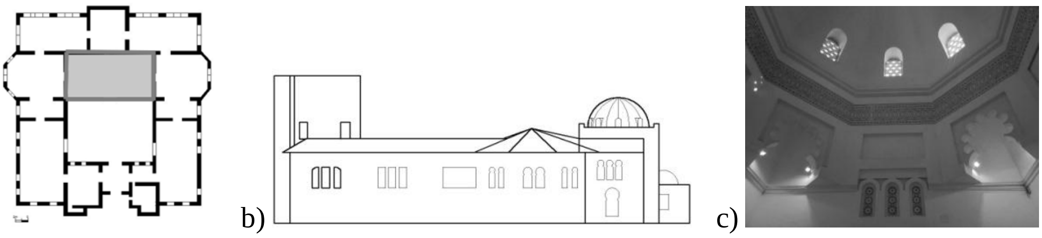


Figure 3: (a) Ground floor (b) Elevation (c) Temporary exhibitions space.

Method

This study was conducted in two major phases: the first based on a literature review of exhibition types, requirements and conditions of expographic lighting quality. Through this literature review, we tried to synthesize the recommendations of the expographic lighting, combining natural and artificial lighting, in terms of "ambient" and "accent" lighting (for 2D and 3D objects). These recommendations have been formulated as a reference tool used in the following phase. The second phase concerned the assessment of expographic lighting quality in three reused museums with the recommendations' filter. This assessment is essentially based on observation, graphic and photographic supports collected by the author.

RESULTS

The following table summarizes, from literature review, the recommendations related to the choice of lighting type, whether natural or artificial, depending on expographic requirements for "ambient" and "accent" lighting.

Table 3. Assessment of natural and artificial expographic lighting in the case studies

		Natural			Artificial				
		Lateral	Zenithal	Polar Oriented	Direct			Indirect	Direct/ Indirect
					Diffused	Focused	Framed		
Ambient		Just Recom mended	Highly Rec.	Well Rec.	Highly Rec.	Well Rec. [1] Less Rec. [2]	Highly Rec. [1]	Highly Rec.	Highly Rec.
Accent	2D	Less Rec.	Jut Rec.	Highly Rec.	Just Rec.	Highly Rec.	Highly Rec.	Less Rec.	Just Rec.
	3D	Highly Rec.	Well Rec.	Well Rec.	Less Rec.	Highly Rec.	Highly Rec.	Less Rec.	Just Rec.

Rec. = Recommanded / [1]For dramatic ambiences / [2] For soft ambiences

Museum of arts and Traditions — Museum of Modern art — Museum of Antiquities

Case 1: The Museum Of Modern Art of Algiers

The “Museum of Modern Art” hosting temporary exhibitions has a number of advantages in term of “expographic” lighting such as overhead natural lighting devices, which theoretically represent the best source recommended for temporary exhibitions. But the devices composed of three large domes and little skylights do not ensure a sufficient “ambient” lighting because of the important height of the atriums, composed of 4 floors (fig.4a). To resort to this weakness, a supplied indirect artificial lighting has been installed with fluorescent projectors oriented to the ceiling (55W/4000K/ IRC>90), direct projectors oriented to the floor (fig.4b) and indirect lighting embedded in the ceiling (indirect diffuse-batten fluorescent luminair- 54W/4000K/ IRC>90) (fig.4d). The central atrium space is then provided with a soft light uniformly distributed. Without the “accent” lighting, the paintings form a single unit with their background. Artificial light plays its substitution but also its widening work role, and meets the needs of “accent” lighting, highlighting the exhibits and offers opportunities necessary for the flexibility of a space welcoming temporary exhibitions. Through rotating spotlights on rails, that ensure the emphasis of artwork with a direct focused or framed lighting (halogen lamps 50W-3200K-IRC100) (fig.4e), it highlights the artworks that stand out from their background, to guide the look toward the artwork, an effect exacerbated by a lower “ambient” illumination (fig.4c). These devices generate a combined lighting predominantly artificial for the temporary exhibitions.

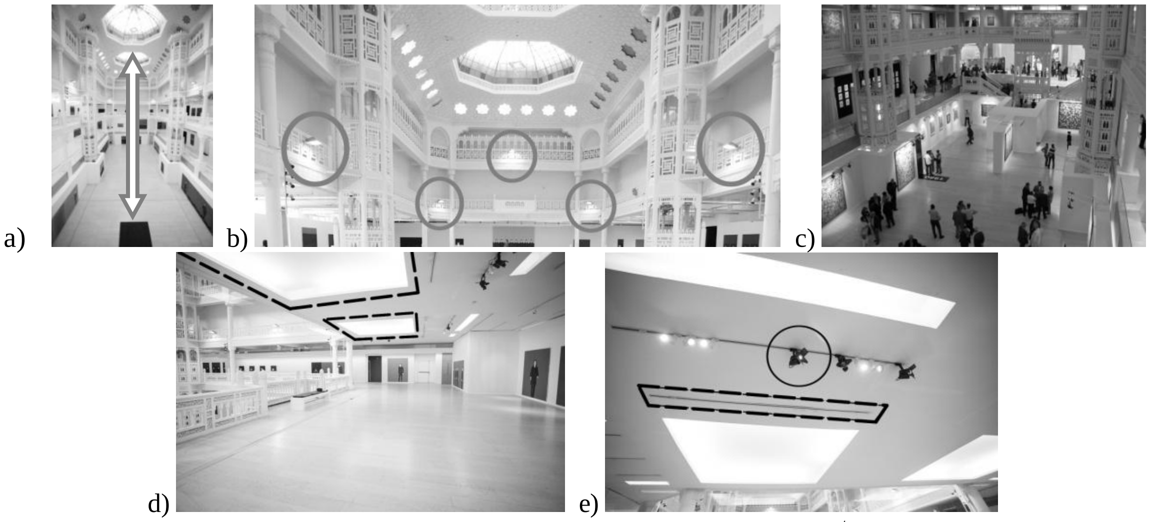

Figure 4: Interior photographies of the museum (atrium and the gallery at the 1st floor).

According to the synthesis table (tab.3), the MAMA museum should meet the "Highly recommended" device for natural lighting, but in reality, with the narrow and deep spatial form of the atrium the natural light is insufficient for “ambient” requirements and completely absent for “accent” expographic requirements. So, deficient natural lighting has been supplied by focused artificial lighting, highly recommended for 2D and 3D objects, adapted to temporary exhibitions that the museum welcomes. Although the artificial lighting ensures adequate expographic lighting, its dominance induces important consequences on the energy consumption.

Case 2: The Museum of Popular Arts and Traditions

The “ambient” lighting is provided by a diffused natural light penetrating through the entrance and windows (fig.5). The lack of artificial lighting here may be a problem when the illumination drops. The “accent” lighting here is provided by adjustable halogen spotlights (20W- 3000K-IRC>90), with direct light focused but illuminating a small area of the space and the exhibits in the showcase (fig.5). The exhibits are mostly three-dimensional and lack “accent” lighting, knowing that the diffuse daylight in this space offers little modeling, especially when the sky is cloudy.

Figure 5: Photographies of the “Algiers” exhibition hall (Permanent exhibition - 2nd floor)

The specificity of this museum lies in the fact that it is a "heritage", with heavy loadbearing walls of historical nature. In this case, the lighting of the building and its architecture is as important as objects that are exhibited. The exhibition spaces here are too small for the collections that are hosted and do not allow the visitor to move back and appreciate the exhibition. According to the table 3, the museum should meet the "highly recommended" devices for artificial lighting, but in reality, the presence of this light does not meet the quality requirements, given the number and orientation of lighting devices, that do not fit the needs in terms of expographic lighting. As for the natural lighting, the only existing device is side lighting, which does not necessarily ensure the level of illumination needed for the exhibition, which would have been suitable for permanent 3D collections of small or average size only. The adaptation of the exhibition to the space should be taken into account by the designers, through the ability of the building to accommodate (structure, accessibility, strength of the frame, etc) with a light that targets the architecture of the building, as well as the exhibits.

Case 3: The National Museum of antiquities

Natural diffused light entering through the windows positioned at an important height (gaining exhibition surface) and featuring a diffusing glazing, helps illuminate the space and the objects that are on display (fig.6a). This natural source is supplied by a direct artificial light, with fluorescent tubes (58W-5250 lm-IRC>80) (fig.6b, c), which remains insufficient in case of illumination drop, given the number of devices and surface space. In this museum, the emphasis of the collection is ensured by natural lateral light which in case of high levels; significant shading patterns are generated on sculptures. In the table 3, lateral natural lighting is highly recommend, but in this case study the high proportions of the sculptures, compared to the space measurements and the windows’ disposal, led to the need of artificial light supply for “accent” requirements. This supply should enhance the exhibition quality of the artworks, but artificial “accent” lighting is only present in the showcase (direct diffused lighting).

a)  b)  c) 

Figure 6: Photographies of the “Christian art” and “Marbles” exhibition halls (Permanent exhibition)

According to the synthesis table 3, the Museum meets the "highly recommended" devices for artificial lighting, but in reality this light does not answer all the quality requirements, in terms of number and type. With the lateral natural lighting, the spaces are only side-lit, which is certainly favorable for some sculptures, but in excess for high sculptures and insufficient for accentuation of small 3D objects and 2D objects. All the “accent” expographic lighting defaults should be corrected by supplying the space with artificial lighting adapted to each space and to each type of objects. In this museum, two main problems arise: the first is the abundance and numerous varieties of museal objects face to the rigidity of the spaces (fig. 6a, c) and the second is the same combined lighting devices existing in all exhibition spaces despite the big variety of the collections. For these permanent collections, improving the combined lighting according to every collection requirements will considerably enhance the expographic quality; but in our opinion, if the museum was adapted to the first collections in 1896, today this important cultural heritage deserves to be hosted in a new building museum with more flexibility and more adapted expographic lighting, specially designed for these collections.

CONCLUSION

Some converted museums offer better expographic lighting than others. Through this preliminary study, it seems clear that the conversion of a building into a museum requires an assiduous appraisal to evaluate the opportunities that the building offers. Strengths and weaknesses should be studied in accordance to numerous factors among which are the exhibition type (permanent or temporal), the collections requirements (2D, 3D, proportions), the conservation requirements and the energy consumption. From the case studies assessment, we retain that more the converted building offer flexible spaces, more it can fit the expographic lighting requirements but with heavy consequence on energy consumption when the natural lighting is insufficient. The Museum of Modern Art of Algiers seems to fit the expographic lighting requirements for temporary collections with the flexible spaces it offers, particularly the central atrium capturing the zenithal natural ambient lighting, even if insufficient. In its category as a museum of temporary exhibition, it seems to be a good example needing extensive study of its artificial lighting in order to reduce the energy consumption. In its category as a museum of permanent exhibition, the museum of Popular Arts and Traditions seems also to be a good example of collections adaptation to the space. The natural lighting is insufficient and the supplying artificial lighting should enhance both the expographic and the historical character of the building. The third museum seems to be the worst example, where spaces don’t fit either objects proportions or lighting requirements. The main recommendations we retain from this preliminary study is that in a reused building, the “natural lighting” should be the first considered and foremost factor to chose appropriate collections and to supply with adapted artificial lighting with energy consumption care.

ABSTR ACT HEADING

How much does it cost to rehabilitate and extend, with optimal conditions of habitability, a non-used building versus starting a new one from scratch?

One of the main challenges we are facing nowadays in order to fight against climate change is the efficient use of resources in all areas of society. From the scopes of architecture and building sciences, the efficiency in the management of resources will be key for improving our capacity of adaptation towards the requirements of sustainable development and climate change. This issue is directly linked to the topic of rehabilitation versus building from scratch (starting with a new floor plan).

The research developed for the thesis "Life cycles of materials. Building from scratch versus rehabilitation and extension of the traditional dwelling from Extremadura" presents values that go far beyond the estimations made for the initial hypothesis; the impacts on the quality of the natural environment of a renewed-extended existing dwelling is 63,42% lower than the impacts generated by building a new one. Specifically in economical terms, the costs of a renewal/extension of an existing dwelling are 36,90% lower than the costs of a new building.

Having these data values, a quite important question is still in the air: Which will be the steps required to be able to acknowledge society about this issue?

We have completed an empirical demonstration in the case study of the dwelling in C/ Colón 36, in Castuera (Spain), where we present the process to obtain satisfactory results using the following methodology:

DECONSTRUCTION + REUSE = NØWASTE

INTRODUCTION

Nowadays, the habitation requirements for dwellings leave out any possibility of renewing traditional housing. Everyone wants to live in a new house, and never think about renewing an old dwelling using popular architectural technics. Although this type of dwelling was already designed with integrated passive architecture, their owners are just either waiting for its collapse or to be demolished in order to build new ones.

Throughout history, in different regions of the world, many cultures have reutilized materials from other constructions to build new dwellings, great buildings, monuments... But after the industrial revolution it is only considered to build using new materials.

We believe it's time to change this paradigm. Some architects have thought of this idea, as we have now the technology for analyzing materials and creating virtual designs before building. That way we are able to calculate if it's feasible or not, and how these materials can be reutilized in order to obtain more efficient buildings. I´ve been working and researching on processes of reutilization and on this type of architecture since 2004. We have worked with passive design, materials reuse, simulation software, Life Cycle Analysis, situated technology and local knowledge, obtaining the best design answers for the needs of its inhabitants. These technics are: DECONSTRUCTION + REUSE = NØ WASTE.

INTENT AND OBJECTIVES OF APPLIED RESEARCH

Our intention is to answer the following question: ¿How much does it costs to renew and extend, in optimal conditions of habitation, a non used building versus a new construction? When we ask "How much does it costs" it refers to economical value but also to environmental impact.

GENERAL OBJETIVE: To determine, through comparison, how much it costs to rehabilitate and to extend, in ideal conditions of habitability, a building in disuse versus a new building: environment impact and economic value.

SPECIFIC OBJETIVE, working on interventions with real projects:

1. Acquiring knowledge about construction system in dwellings from Extremadura (Spain).
2. Acquiring knowledge about construction systems in new dwellings.
3. Assess the materials and construction systems to be efficiently reutilized in dwellings renewal.

METHODOLOGY AND TOOLS

The methodology is based on the following processes: search of bibliography, search of data bases (demography, climate, materials, construction details and local technology), analyzing traditional construction systems in Extremadura and in projects of new dwellings built from scratch.

The tools used for obtaining these results are:

1. SIMAPRO (ECO-INDICATOR 99); valuation of damages in several areas of impacts:
   1. Human health: expected years of life adjusted to disabilities, used on the World Bank and in the World Health Organization. (W.H.O.).
   2. Ecosystem Quality: (m2·yr·PDF) square meters of surface of vegetal mass that will endanger some species that may potentially disappear
   3. Resources: Megajoules needed to obtain low quality minerals and fossil fuels in the future.
2. ARCHISUN: acquiring and comparing values of energetic consumption in dwellings after built.
3. Price basis of Extremadura: overview for comparing the costs in € between the following case:
   1. Unused dwellings after renewal and extension.
   2. New dwellings built from scratch.

OUTCOMES AND COMPARATIVE

In this research, we have compared two cases to be able to know the impact and economical cost in each construction unit, but also the energetic costs after finishing the construction process. The analyzed buildings had similar dimensions, but for a better comprehension and comparison, in the impact analysis we have work with built square meters. This way we managed to work with exactly the same measurement on each construction unit, as normally each material is measured in different units (concrete: m3; steel: Kg; brickwork: m2; etc...).

First, we have evaluated the damages created in the quality of the natural ecosystem. Each building has similar installations (bathroom, kitchen, living room, sleeping rooms, etc...), therefore, we are analyzing only six construction units (soil movement, foundations, structure, brickworks, finishes and roofing), because these units have the largest differences when analyzing the impact. More information can be found in "Ciclo de Vida Material. Construcción de nueva planta versus rehabilitación y ampliación en la Vivienda Popular Extremeña". This work has been developed in "La Serena", which is a region in the south east of Extremadura (Spain). We show the general comparison of these two types of constructions. On a second phase, we have analyzed the energetic expenses after the construction process was finished, this way we can value how efficient is each type when they´ll be used. The data is showed per year, in a 50-year life cycle. Finally, we present one of the most important issues for our society, the economical value, answering the main question for this research.

Comparative of Ecosystem Quality impact

The comparative analysis of the case studies (new dwelling versus renewal-extension of a dwelling) is presented by categories and areas. With the obtained results, we can understand that renewing and extending a dwelling has less impact than building from scratch. A first graph shows the impact in several areas (human health, quality of the natural ecosystem and resources).

In all areas, the damage by square meter in renewed and extended dwelling will be 60% lower than in a new construction. In terms of quality of the natural ecosystem, it's 2,7 times lower than in the worst case scenario. For human health is 3,45 times lower, and for resources it's 3,13 times lower than what is produced by square meter compared to a new dwelling built from scratch.

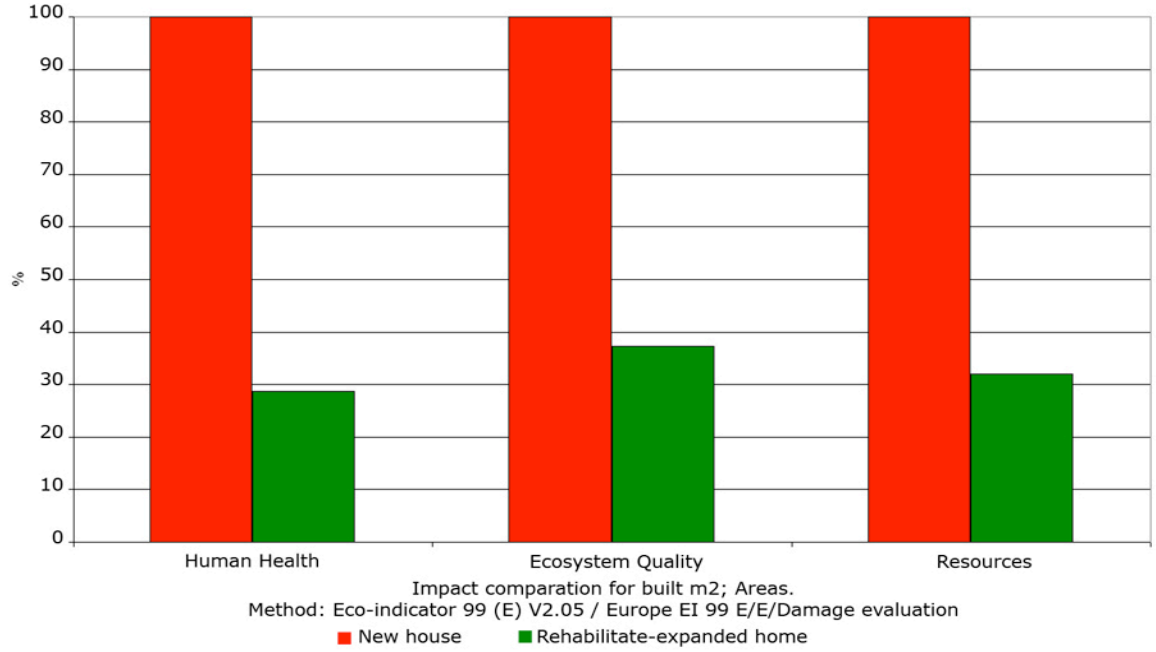

Figure 1: *Impact comparison by areas between new dwelling and renewed-extended dwelling*

In the graphic of comparison by categories, we can find the specific impact in kg.eq.CO2 emitted by each square meter and we can see the originating causes. This graph shows three categories that are more relevant than the rest (from lower to higher): climate change, inorganic breathing particles and fossil fuels..

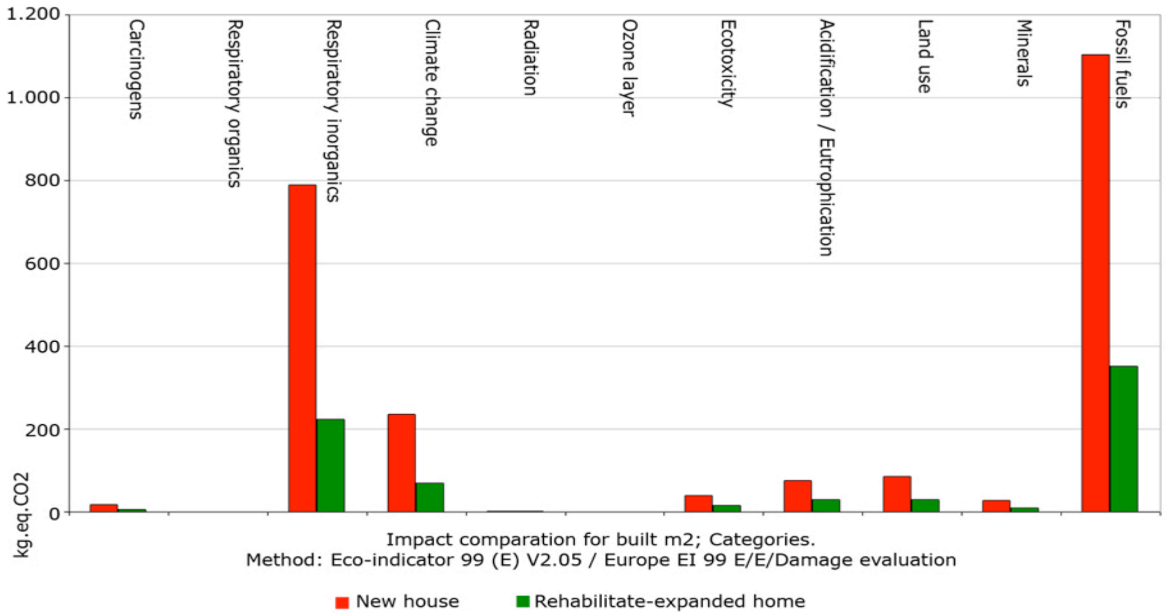

Figure 2: *Impact comparison by categories between new dwelling and renewed-extended dwelling*

This research has the exact value for each construction unit, for more information please consult on the book. Now, for a better comprehension, we show the uncertainty graph of Monte Carlo. This way we will know which are the originating causes for the emission of kg.eq.CO2 on each category for new dwelling or for a renewed-extended dwelling. In the analysis, the values from the renewed-extended dwelling (green) are subtracted to the values of the new dwelling (red).

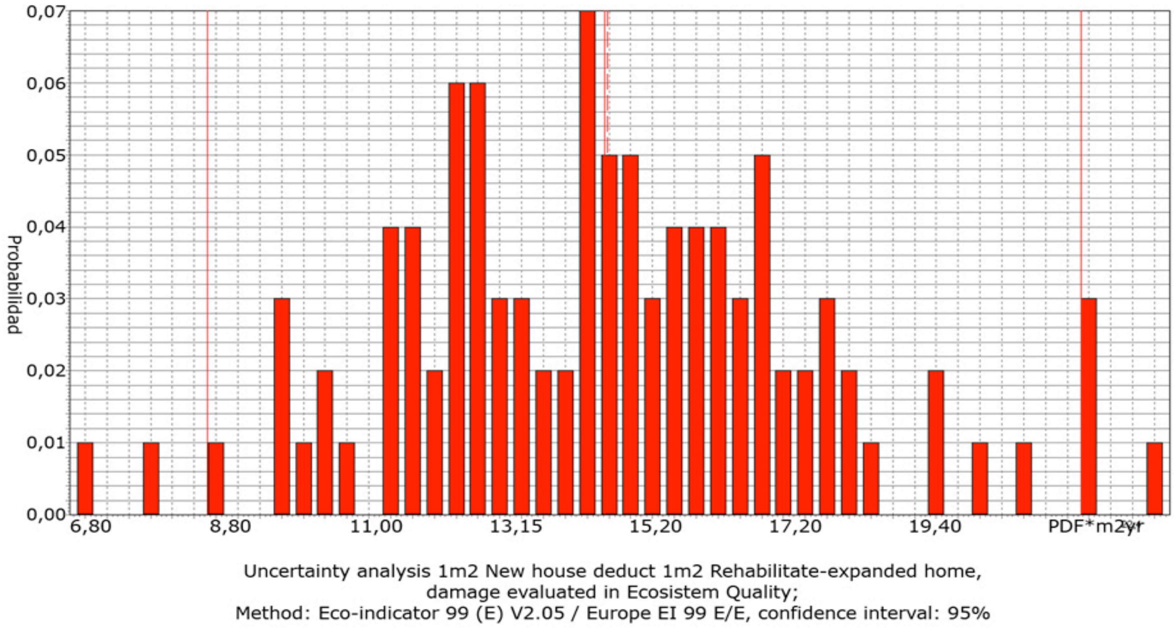

Figure 3: Uncertainty analysis. Impact on the quality of the natural ecosystem for each m2 built of new dwelling versus m2 of renewed-extended dwelling.

In the comparison, there are construction units with a proportional relationship lower than 9,35 times. It's the case of brickwork and roofing. The reason for this is that in these units, most of the materials are reused form other constructions or from the renewed dwelling itself (bricks, roof tiles, sand, clay, wood or sticks). In the case of the external finished, the relation is 2-3 times, because even if we reutilize sand and clay we need lime to make the mortar (in some cases, we will need cement and steel too). Lime has a lower impact, but this material (and it happens the same with cement) requires transformation process to be able to use it for construction. Finally, our goal for this research study in the comparison between new versus renewed-extended and this last aspect (extension) is the reason why there is a bigger impact in this unit, **as shown in Table 1.**

Table 1: Uncertainty comparative newly built dwelling and a renewed-extended dwelling (Kg.eq.CO2)

	New house	Renewed-extended dwelling
Foundation	7,060	4,790
Structure	14,640	7,060
Masonry	9,650	0,770
Roof	6,480	0,700
Cladding-finishes	7,430	2,790
TOTAL SUM	45,260	16,110
All built work package	**45,58**	**16,67**

The average value of the total comparison shows that each square meter of newly built surface has a level of emissions of 2,73 times versus surface of a renewed-extended dwelling. Also, with an approximate calculation, we can obtain a comparative value of new versus renewed; if the dwelling is not extended, we need don't need to make new foundations. In this case, the square meter of renewed dwelling has 4,79Kg.eq.CO2 less of emissions. If we subtract in the structure of the building a part of the concrete, steels and pre-fabricated elements, the renewed dwelling will have an impact 75% lower. This way, the emissions of Kg.eq.CO2 generated by the structure would be 1,82. In other construction units we should also subtract some elements, but these data values are enough to demonstrate how much lower the impact would be. Still, discounting these values, renewing a dwelling would generate 6,08Kg.eq.CO2 versus 45,26Kg.eq.CO2/m2 of the new construction. Therefore, we can see how the impact of the renewal would be much lower; precisely 7,24 times lower.

Comparative energy consumption after construction.

The ARCHISUN analysis will give us the energetic expense for each construction, and it shows that the renewed-extended dwelling has a better behaviour. Normally, people think that an architecture renewal performs worse than a new dwelling, but as we see in the following table, it can be seen how this popular concept is wrong, it all depends on a good design before constructing or renewing. Considering that both projects were thought of as efficient designs, we can observe more favorable values when we renovate re-using local materials versus building with conventional materials (concrete from a factory, steel from who knows where, wood form another continent, etc...).

Table 2: Comparison of energetic consumption once the construction works are finished

GENERAL DATA	NEW HOUSE	RENEWED-EXTENDED DWELLING
Volume:	893.00 m^3	840,96 m^3
Peoples:	4	4
Building use::	permanent housing	permanent housing
Median temperature sensation winter:	10.89 ºC	11,63 ºC
Median temperature sensation spring:	22.41 ºC	22,93 ºC
Median temperature sensation summer:	31.10 ºC	31,58 ºC
Median temperature sensation autumn:	24.14 ºC	24,44 ºC
Natural light	7.55 lux	9,87 lux
Acoustic insulation	26.31 dBA	25,61 dBa
Heating:	10.61 kWh/m3 year	4,98 kWh/m3 year
Refrigeration:	4.50 kWh/m3 year	3,60 kWh/m3 year
Lighting:	4.13 kWh/m3 year	4.12 kWh/m3 year
Hot water:	2.28 kWh/m3 year	2,36 kWh/m3 year
Kitchen:	2.01 kWh/m3 year	2,14 kWh/m3 year
Others:	1.29 kWh/m3 year	1,30 kWh/m3 year

Comparative economic cost.

In the current society, this is perhaps the most important comparison for the citizens. We are talking about money, most of the time or maybe always, it's the only issue apparently. Again, as in the previous cases, the table shows that the dwelling built from scratch is more expensive than the renewed dwelling. Therefore, the good values are not only related to the impact in the quality of the natural ecosystem or the energetic expense after the construction process, it also happens in economical terms.

Table 3: Costs comparison between each type of construction. These prices include the costs of labour, materials and required machinery for each construction unit. http://basepreciosconstruccion.gobex.es/

SUMMURY CONSTRUCTION UNITS	NEW HOUSE	RENEWED-EXTENDED DWELLING
P001- Deconstruction and previous work	- €	5.988,59 €
P002- Earth movement	979,03 €	5.864,77 €
P003- Foundation	8.330,88 €	23.646,07 €
P004- Sanitation installation	2.166,87 €	2.215,43 €
P005- Structure	28.486,30 €	5.460,42 €
P006- Masonry	17.487,20 €	7.793,80 €
P007- Cladding-finishes	22.374,43 €	2.244,72 €
P008- Roof	21.884,84 €	2.623,68 €
P009- Paint	4.670,55 €	2.298,96 €
P010- Electricity installation	5.042,32 €	6.679,42 €
P011- Plumbing installation	7.095,49 €	8.392,19 €
P012- Doors and windows	20.436,12 €	11.269,85 €
P013- Locksmith installation	224,75 €	2.773,86 €
P014- Security and health	1.256,52 €	1.238,76 €
BUDGET EXECUTION MATERIAL	**140.435,30 €**	**88.490,52 €**

The most important differences are in the three first units (de-construction and previous works, soild movements and foundations). This happens because in the renewed-extended dwelling included a new basement, therefore these construction units are more expensive. In the rest of cases, reusing materials is cheaper and the most important issue to obtain reduced prices is in the construction. These budget estimations do not include yet the costs of quality control and taxes (porportional for both cases).

INFERENCES AND CONCLUSION

With all the data obtained we can see that the renewed-extended dwelling is cheaper than the newly build dwelling. It is important to understand that we need a well designed process of de-construction and re-utilization of materials to be able to obtain these good results. In a renewal process we first need to know if the existing building is in a ruin condition; this will be a main requirement for the proposal. A building will be considered to be in a ruinous condition when it presents large structural damages or when in needs a partial reconstruction of over 50% of the building. If the existing building is in a ruinous condition, it will be better to completely de-construct it and to re-use the obtained materials in a new construction, either on the same location or in other location, but not too far, in order to reduce the impact in the quality of the natural ecosystem.

The values previously shown give us the knowledge to be able to answer our questions regarding impact on the quality of the ecosystem and the economical costs of building a new dwelling or renewing-extending an existing dwelling:

1. Impact in the quality of the natural ecosystem in a new dwelling is 2,73 times larger than in a renewed-extended dwelling. It is important not to forget that, if we just renew, the impact of a new house will be 7,26 times bigger for each square meter built. The Kg.eq.CO2 emissions are proportional; each square meter of new dwelling will have 45,58 versus 16,67 in a renewed-extended dwelling. This means the **Ecosystem Quality impact is 63,42% less.**
2. The economic cost of a new house (140.435,30€) versus a renewed-extended dwelling (88.490,52€) is **36.9% cheaper**. Any person would want to renew a dwelling if they knew that the costs are lower than purchasing a new house.

EMPIRICAL DEMOSTRATION, APPLIED RESEARCH, PRACTICE WORK.

We decided to work at the neighbourhood called "El Cerrillo" (Castuera, Spain). It's the oldest and most traditional area of this village. We investigated private and public spaces, types of dwellings, age,

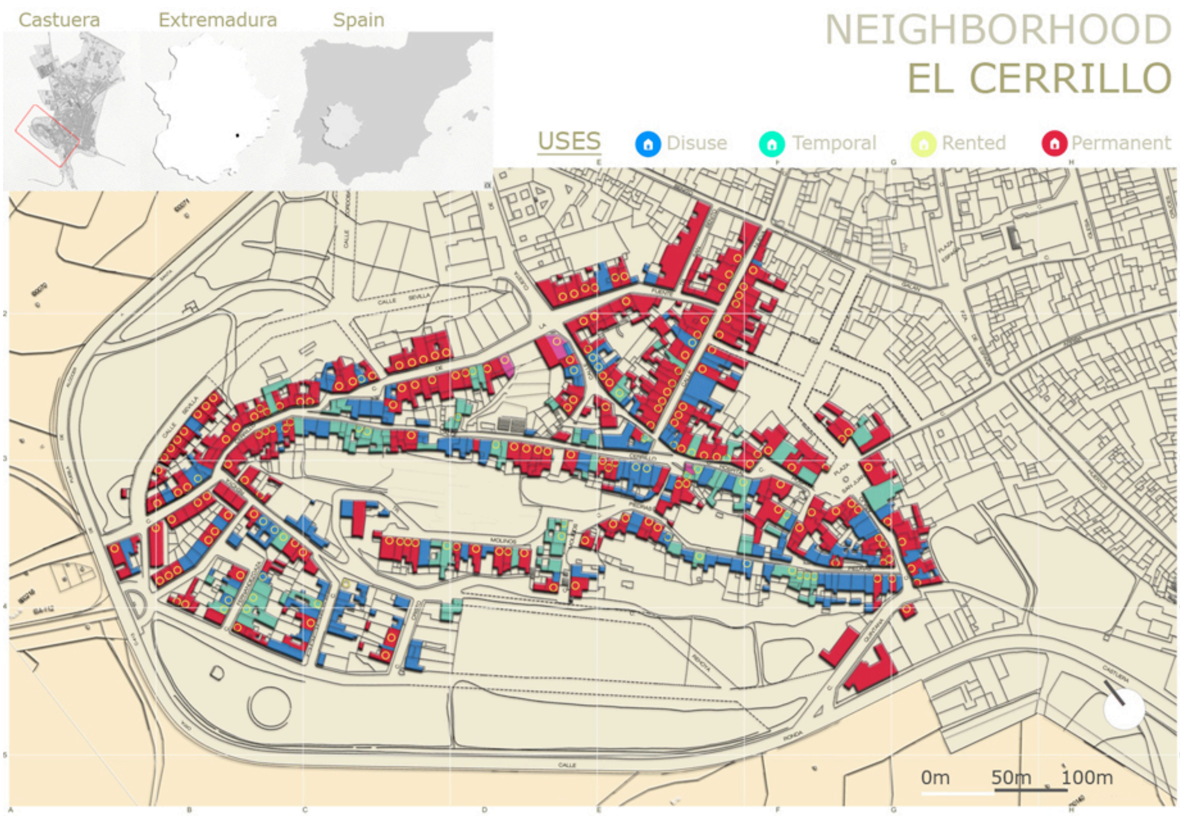

Figure 4: *Used and non-used dwellings in the neighbourhood of "El Cerrillo" (Castuera, Spain)*

materials and the most important of all, the quality and the potential of each dwelling. We found 407 dwellings, 222 with permanent use, 112 non-used and 73 dwelling in rental regime or temporal use.

Many dwellings are in good conditions and a renewal process would be feasible. That is why, in the following step, we went to dwelling built upon traditional and popular technics from Extremadura, where we can work and obtain empirical results about DECONSTRUCTION + REUSE = NØ WASTE.

We worked at the dwelling located at C/Colón 36 (Castuera, Spain). The goal is to un-build the roof (tiles, soil, sticks, wood desks, nails and wooden beams) and adobe walls; **as shown in next figure.**

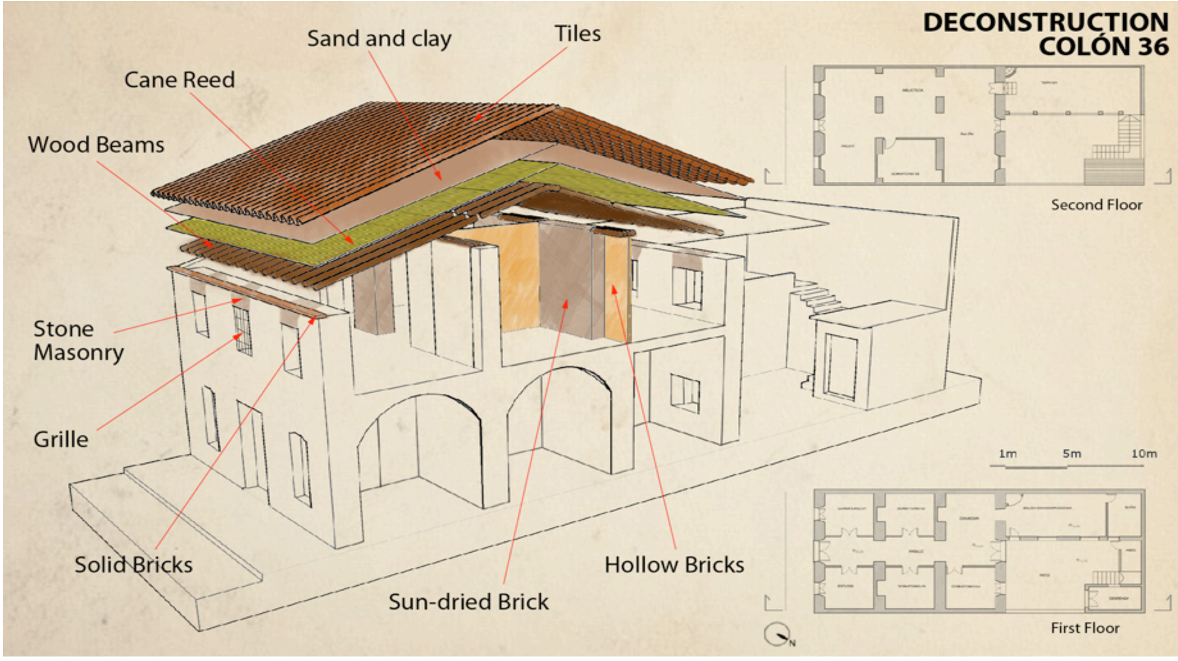

Figure 5: *Deconstruction process.   www.architectureindevelopment.org/project.php?id=354*

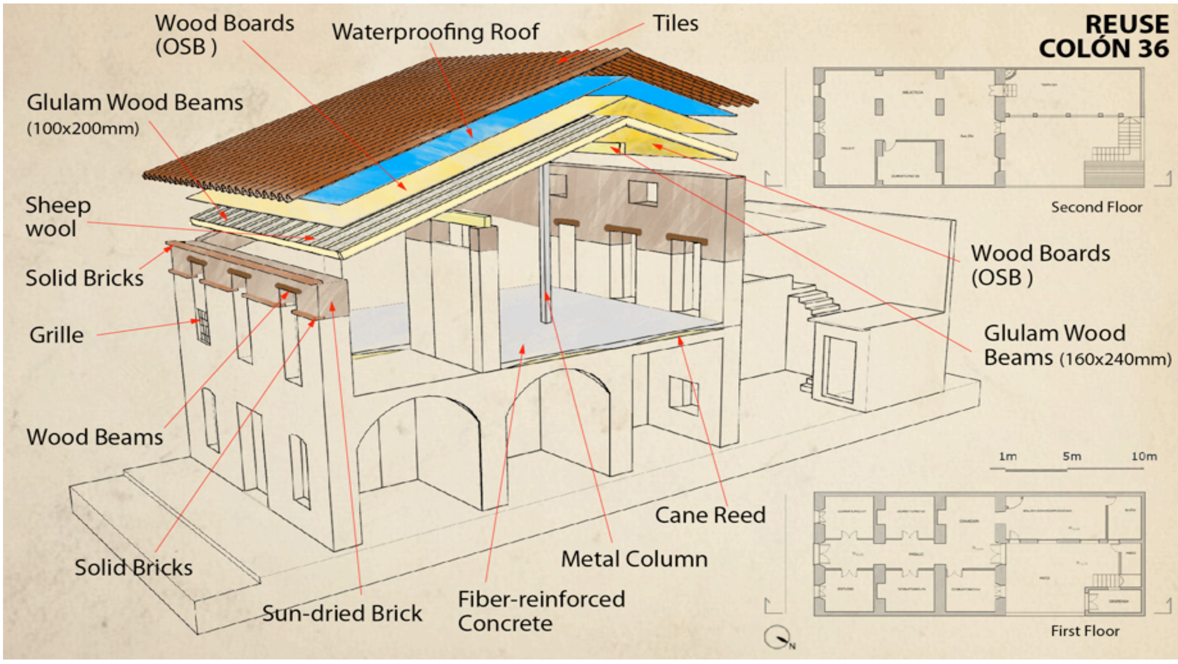

Figure 6: *Reutilization processes.   www.architectureindevelopment.org/project.php?id=354*

Before deciding for the reutilization, we test the materials (trength and durability). We will be able to reutilize 65% of the roof tiles for the same function, and the rest for different functions than the original one (filling up walls, or noise isolation in the fundations). The adobe can be used to increase the walls in the perimeter. Soil as a fill up material in walls, to join the adobe with the facade mortar. The sticks were used as formwork, creating the dome to improve the weight distribution in the structural part of the 2nd floor and carry the loads to the walls of the first floor.

Wood beams to make windows and door lintels and support wood pieces **as shown the Figure 6**. The clapboard and nails were used to build alveolar slab wood, where we use new wood boards (OSB) and glulam wood beams. The insulation is solved with natural sheep wool, using local materials.

Thus, we obtained our goal, this is one of the many works that we have done, after research "Ciclo de Vida Material", we have done in Proyecto áSILO; with the hope that these results can be useful in other parts of the world.

Building a Generic Methodological Framework for a Sustainability Tool Tailored for Architect-Designers

Bart Janssens

Faculty of Design Sciences – University of Antwerp, Belgium

bart.janssens@uantwerpen.be

ABSTRACT

Success in sustainable building depends on a number of factors. Within the competency of project participants, it is crucial that architect-designers have the knowledge and ability to adopt the issues of sustainable building into their designs. An approach on the way towards sustainable architectural designs is to apply methods and tools. These tools aim to act as a bridge, an interface between scientific proven knowledge and the daily practice of architect-designers. Although the use of sustainability tools by design teams is increasing, the present state of contemporary designs regarding the full scope of sustainability indicates a gap, an inadequacy of existing tools.

The target of this research is to build a generic methodological framework for a sustainability tool specifically tailored for architect-designers. First, a literature study identifies specificities of determining factors, resulting in supposed criteria for aimed tool. Second, a review on existing kinds of sustainability tools is carried out. Synthesized issues are pointed out and the assumed inadequacy is verified. Third, an outlook is proposed. Based on identified criteria and issues, a presumed promising concept for aimed tool is delimitated and a set of starting points for the further development are selected. Finally, a proposition for the generic methodological framework is formulated.

The result of this exploratory study is a confirmation of the hypothesis that prevailing up front kinds of sustainability tools are inadequate for architect-designers. Suggested generic methodological framework is seen as a possibility for the development of an operational sustainability tool specifically tailored for architect-designers.

INTRODUCTION

The demand and urge for sustainable development has been increasing the last decades. Due to the multi-dimensional complexibility of the concept of sustainable development in combination with the complexibility of the building sector, the gradation of multidisciplinarity and the size of project teams are expanded. In response, the need for well-understood planning and design processes of sustainable built environments has also been increased (Abdalla et al., 2011).

On the top of critical success factors for delivering a sustainable project is the competency of project participants (Bakar et al.). Whatever the ‘project delivery system’ is, it is seen that the architect-designer fulfills a central role in the project team (Molenaar et al., 2009). As a consequence and by extension, it can be stated that the architect-designer plays a crucial role in delivering sustainable built environments.

A generic and ever expanding approach on the way towards sustainable building is to apply methods and tools. These enable the planning team to identify the effects and interactive relationships of social, economic and ecological dimensions, and deal with these in the planning and/or construction process. (Hegger et al., 2008, p.191). Despite the huge range of tools on the market, the awareness of their existence and the increasing implementation by project teams, the built environment still indicates a gap regarding sustainability. This gives rise to the presumption of an inadequacy of existing methods and tools for sustainability. Given the earlier stated central role of the architect-designer, this inadequacy could be related to incompatibilities, and/or contradictions between the user and the method / tool.

Given a transition towards a sustainable built environment is necessary and architect-designers display a wavering approach, a specific tailored tool for architects is desirable, advisable, and could be successful. The primary objective of this paper is the development of a generic methodological framework for a sustainability tool specifically tailored for architect-designers.

In order to develop a tailored tool, the aimed user has to be known, identified and recognized. First, a literature study identifies specificities of determining factors, resulting in supposed criteria for aimed tool. Second, a review on existing kinds of sustainability tools is carried out. Synthesized issues which the aimed tool should address are outlined. Third, an outlook is proposed. Based on identified criteria and issues, a presumed promising concept for aimed tool is delimitated and a set of starting points for the further development are selected. Finally, a proposition for the generic methodological framework is formulated.

This paper adds to the knowledge of sustainability tools. By explicitly taking into account and focusing specific features of the architect-designer and the process of designing, it stresses the need for a new approach for, and development/ discussion of tools within the field of architectural designing.

This paper is derived from the first part of an ongoing doctorate dissertation on sustainable group housing projects (Janssens, ongoing). This specific research is an explorative attempt for the building of aimed generic methodological framework rather than a research with strict conclusions. The outcome is tentative and preliminary and needs further discussion and verification, both in the fields of academics and practitioners. Outcomes highly depend on conducted literature study of selected corpus of sources, and are not supposed to be salutary or the only possible ones.

DEVELOPMENT OF SUPPOSED CRITERIA FOR AIMED TOOL

Identification of influencing factors

Following aspects are believed to affect the composition of criteria: 'the architect-designer' as the actor, 'designing' as the activity, 'the built environment' as the object and finally the aim of 'a sustainable development'.

The object: the built environment. The built environment relates people to spaces through built forms. It ranges in scale from interiors, buildings, neighbourhoods to districts and cities, including their supporting infrastructure. It refers to a broad-ranging interdisciplinary field that addresses design, construction, management and use. The built environment could be defined as the human-made space or surroundings that provide the setting for human activity, live – work – recreate, on a day-to-day basis. It comprises an infinite variety of functions to meet the endless range of human interests and proclivities. In another sense, the built/constructed environment involves some of the most elaborate forms of artifice—varieties of materials, complex engineering, infrastructures of technical interconnection and relationships to nature. The built environment refers to a practice-oriented discipline, in which the end product is a material, spatial and cultural product of human thinking and labor, taking into account interactions among the constructed, social and natural environments.

The aim: sustainable development. The essence of sustainable development is to provide for the fundamental needs of humankind in an equitable way without doing violence to the natural systems of life on earth (Kemp & Martens, 2007). Following Our Common Future (WCED, 1987), numerous efforts were made to operationalize the concept. The most common is the triangular representation with three pillars 'environment', 'society' and 'economy'. In some contexts these pillars come to be referred to as 'Planet, People, Profit' (Elkington, 1997).

Concerns for the relationship of humans to environment, natural and built, increasingly deploy the rubric of sustainable development, making it one of the fundamental concerns of contemporary times. The definition of Our Common Future has been interpreted in many ways, caused by the fact that the vision and the description are linked to many different aspects. Some interpretations give the notion that sustainable development is a specific field or discipline, other emphasizes the dynamics emerging from different imperatives. Either way, the vision concerns complex, multi-disciplinary problems that have to be handled from both holistic and analytical approaches.

The activity: designing. Despite real differences between the end products created by designers in various domains, design can be seen as a generic activity: ‘Many forms of design then, deal with both precise and vague ideas, call for systematic and chaotic thinking, need both imaginative thought and mechanical calculation’ (Lawson, 2005, p.4). Nevertheless considerable revisions about design theory, several authors claim that our current understanding of design is still incomplete. This does not imply that designing is mysterious and obscure, but that it is complex (Lawson, 2005). Tjallingii (Tjallingii, 1996) states that designing is the creation of promising combinations and opportunities regarding the physical context, the use and management.

The actor: the architect-designer. The working field of the architect-designer is the built and yet to build environment, ranging in different scales and specialties. Literature is vague and apparently no one feels able to offer a succinct description that they are confident would be widely agreed upon and yet fully describe the work of all architects. Lawson (Lawson, 2004, p.1) states: ‘It is quit impossible to find two people who call themselves architect and yet hardly share any of their daily tasks’. Following Lawson (2005, p. 4), the working field of the architect-designer lies near the middle of the spectrum of design activity. Design in the built environment requires both technical knowledge and expertise, as well as visual imagination.

Pinning down synthesized features of actor and activity factors

Factors of the actor (the architect-designer), and the activity (designing) are complex and heavily loaded. A commonly accepted defined framework is inexistent. However, for the purpose of this research, a self-compiled set of widely subscribed features was made, backed by selected corpus of relevant sources. Synthesized features are provided in table 1. Within the scope of this paper, providing referencing notes on displayed features is not possible. Therefore only general references are given: Cross, 2006; Lawson, 1980; Lawson, 2004; Lawson 2005; Rehal, 2002; Van Dorst, 2005.
Classified features may not be seen as strict, as there is a strong overlap in, and interdependence of, characteristics of the ‘architect-designer’ and ‘designing’.

Table 1. Synthesized features of actor and activity.

The actor: ‘the architect-designer’	The activity: ‘designing’
Explicit & implicit knowledge	Exploratory & satisficing
Different levels of expertise & experience	Responsive & integrative
Complexity management	Convergent & divergent
Solution focused	Resultant, emergent & abductive
Metaphoric appreciation	Reflective (simulating) & ambiguous
	Iterative, personal & unique
	Narrative & imagery

Cross-factor reflections

Sustainable building is a combination of disciplines, a necessary package deal to prevent us from trade off effects. This complexity describes the problems of sustainable development and at the same time shows the daily practice of an urban designer or planner. The practice of finding ‘promising combinations’ (Tjallingii, 1996) is the common ground for sustainable transition and design. In a designerly way of thinking one combines possible solutions from disciplines which are by nature different (Van Bakel, 1995) (Cross, 2006).

In both aspects, built environment and sustainable development, there are no right or wrong answers. Actions must be decided in process of negotiation and dialogue, and the long-term perspective is central within the quest. Lundeqvist (1995) and Edén (2002) conclude that features of sustainability resemble, in general, any traditional design problem. Because the similarities between features of the built environment and sustainability, and the architect-designers ability of dealing with complexibility and multi-disciplinarity makes him suitable to deal with the sustainability quest. Despite sustainability is often dealt by, or pushed off to, a wide range of project partners, the architect-designer can and should take up the mandate in view of sustainable successes in a designerly way. Both aspects, sustainability and the built environment, are so complex that chances for success largely depend on the knowledge, a deep understanding and experience of the architect-designer. It is important that this knowledge and experience building is supported, made possible and not prevented or penalized.

Supposed criteria a tool should comply

This final subsection provides an overview of criteria which a sustainability tool for architect-designers is supposed to comply with.

Table 2. Supposed criteria for aimed tool.

Supposed criteria	Description
Random usability	• No mandatory, design activity structuring successive process: free timing of startup, enter and use, free consultable, allowing an iterative, cyclical or linear process. • Allowing using different design approaches. • Serving an incremental and radical optimization of (yet to be) designed / built environments. • Meeting architect-designers' diversity: suitability to preferences and difference in levels of expertise.
Apprehensible communication	• Ensuring a transfer of knowledge and insights to the architect-designer (primary user of tool). • Ability to act as a discussion platform for project actors. • Providing an attractive/suitable display and representation of the content (photo, sketch, ...).
Problem framing	• Providing background information: identification, structuring and limiting of the problem. • Setting boundaries for the design problem (and solution): support the development of the brief. • Connecting partial problems, mutually and with the design process.
Solution focused moving	• Displaying principles, measures, concepts, combinability's. • Providing non- and contextualized exemplary solutions: single, multiple and/or integral oriented.
Source of knowledge and insights	• Inclusion of scientifically and practically proven knowledge. • Linking theoretical knowledge with practical relevance.
Enabling innovation	• Indicating the need and importance of verifying displayed facts and building episodic knowledge/insights • Stimulating knowledge building by designing. • Incorporation of incentives for own research.
Non-limiting	• Safeguarding creativity and unicity of design/project. • Space for interpretation, implicit knowledge/experience. • Balancing between prescription and freedom/voluntariness: open-ended / non-committal. • Indicating the non-restrictiveness of displayed substantive body of knowledge.

DETERMINATION OF ISSUES OUT OF EXISTING KINDS OF SUSTAINABILITY TOOLS

Identification and description of existing kinds of tools

As there is no strict classification of tools, for the purpose of this section, we suggest a threefold classification. Knowledge based or qualitative tools involve instruments providing guiding principles (e.g. 'Trias-model') on the one hand and guidelines (e.g. 'Practical Recommendations for Sustainable Construction' of the EU) on the other hand. Both kinds are based on proven knowledge and experiences.

Guiding principles offer a simple structure which has to lead to sustainable successes. They formulate generic recommendations, strategies, etc. Guidelines link sustainability in a direct way to decisions, but without offering a structure for the design process. Checklists, catalogues and directives often include targets, criteria and/or measures which can be considered or must be implemented to match set requirements. Performance based or quantitative tools include life-cycle impact assessment, outdoor and indoor social and environmental quality. Quantitative tools can focus on single or a limited amount of sustainability criteria or on multiple criteria. Single or limited sustainability oriented tools (e.g. EcoQuantum) are often developed for scientific research. Aspects of sustainability are clearly defined and demarcated (e.g. energy, material). Multi criteria tools (e.g. BREEAM) are focused on the use by practicing actors in the building sector, aiming to be implemented in practical real-life applications like buildings and neighbourhoods. A matrix assists designers in identifying design criteria, document proposed design performance and calculate the number of achieved credits, leading to an overall rating. Performance based tools, more in specific market oriented tools, can also include a rating system, often supplemented with a certification system and labelling. These labels are used in view of market positioning, recognition, publicity and entitling/obtaining funds, fiscal benefits, subsidies, grants etc.
Ad hoc tools are project specific developed tools. They can be qualitative or quantitative, or a combination of both. Usually these tools are initiated on the occasion of a large scale project like urban regeneration programs, and new neighbourhoods/districts (e.g. PIMWAG-system ECO-VIIKKI, Helsinki, Finland).

Analysis on prevailing strengths/weaknesses and synthesized issues

An exhaustive analysis with regard to displayed classification of existing kinds of tools is not a goal in itself. A quick suitability scan in a general perspective leading to strengths and weaknesses enables uncovering issues. Table 3 provides an overview. Consulted authors are: Abdalla et al. (2011), Gowri (2005), Janssens (2013).

Table 3. Prevailing strengths and weaknesses of existing kinds of tools and synthesized issues.

Kind of tool	Strenghts	Weaknesses
Knowledge based tools (qualitative)	• Informative • Assistance in decision making • Preserve freedom and creativity • Mapping sustainability aspects on to components, indicators, measures, etc.	• No / limited and inadequate insights in mutual relations in and between theoretical and practical aspects • Vague descriptions • Comprehensive elaborations
Performance based tools (quantitative): Multi criteria	• Presumed integrality > • Presumed accessibility > • Indicator for quality's > • Measuring is knowing >	• Limited sustainability scope • Degree of expertise required • No guarantee for successes • Dubious quantifiability of criteria / scoring / weighing • Focus on criteria / indicators • Often misused as checklist
Ad hoc tools	• Project specific tailored >	• Shadow of exclusiveness, exceptionality which is a burden for mainstreaming
Overall	• Identification and definition of sustainability, enabling communication and negotiation	• Dubious effectiveness, efficiency, complexity reduction, up-to-dateness • Susceptible to subjectivity • Extensiveness
	Synthesized issues Preserving objectivity - Providing insights - Attention for manageability – Actual Integrality - Being inspirational	

OUTLOOK FOR A SUSTAINABILITY TOOL FOR ARCHITECT-DESIGNERS

Suitability review and delimitation of a presumed promising concept

This subsection verifies the suitability of two mainstream kinds of tools using two short quotes from literature.

'*The so-called educational tools, including guidelines, rules-of-thumb and best practices seems to be more coherent with the architectural practice, in which the construction of knowledge and decision making is strongly based on referential procedures.*' (Albuquerque, 2007)

'*However, the methods of science are perhaps surprisingly unhelpful to the designer. Modern building science techniques have generally only provided methods of predicting how well a design solution will work. They are simply tools of evaluation and give no help at all with synthesis. Daylight protractors, heat loss or solar gain calculations do not tell the architect how to design the window but simply how to assess the performance of an already designed window.*' (Lawson, 2005)

Design tools are a somewhat controversial subject for architect-designers. Many architects dislike talking about their work process in terms of methods or tools, because it suggests a repetitiveness that is contradictory to creativity. It must be obvious that the specificity of architects, their design methodology and the complexity of designing is so individual that it is impossible to discover an existing or develop a tailored 'tool' which satisfies all. '*Designing is far too complex a phenomenon to be describable by a simple diagram.*' … '*The word "design" is applied to an extraordinarily wide range of activity include at one extreme something that could also be called "engineering" and at another something that could also be called "art".*' … '*Design is a highly personal and multi-dimensional process.*' (Lawson, 2004)

Delimitation of a presumed promising concept

Weaknesses of existing kinds of tools, synthesized issues and previous suitability review gives rise to the development of an innovative concept for aim framework.

- Focus on pre-design and early design considerations and later design inspiration
- Physical – spatial approach instead of a constructive technical approach
- Knowledge based instead of performance based
- Design supporting instead of design process structuring
- Solution focused instead of problem focused
- Knowledge building instead of full exhaustive and limitative display

Selection of a set of starting points for the further development

A description of the complete set of starting points is not possible within the limited length of the paper. As these starting points represents the basis of the further development of presumed promising concept, they will be discussed and documented in depth during the oral presentation. By way of illustration, two important starting points are outlined in this sub section.

General model of high level creative strategies in design. Three key aspects appear to be common in the creative strategies exercised by designers (Cross, 2006). First, taking a broad 'system approach' to the problem. Rather than accepting narrow problem criteria, often set by the client or e.g. regulations, aiming for high-level problem goals. Second, 'framing' the problem in a distinctive and sometimes rather personal way, stimulating and pre-structuring the emergence of design concepts. Third, designing from 'first principles'. Designers either explicitly or implicitly rely upon 'first principles' in both the origination of their concepts and in the detailed development of those concepts.

The phenomenology of concepts. Ramirez (2000) finds it appropriate to operate with three kinds of concepts: ideological, diffuse and compact concepts. The ideological concept hides and idealizes preferred ideas, notions and situations which are desired and may be realistic. Typical political rhetoric is very often dominated by ideological concepts, such as freedom, sustainability, quality, equality and so forth. Diffuse concepts are somewhat ambiguous and often need to be connected to a particular context, situation or experience to be understood. Diffuse concepts refer to phenomena that really exist but are difficult to precisely describe through definitions. Compact concepts are used in science where the studied object is the concrete material world and where unambiguous, well-defined definitions and context independence are the central characteristics. While the built environment is interdisciplinary, all three kinds of concepts are necessary in de design process, whereas a specific order is relevant. Rehal (2002) states: 'In the earlier stages of the process, it is mostly diffuse and ideological concepts that are in focus. When the artefact begins to take shape, the thought process transgresses from diffuse concepts to more compact ones.' This way, concepts are used appropriate to the design stage. Complexity and subjective matters (such as aesthetics, culture, artefacts) which ought to be negotiated during the design process, are kept open as long as possible. The further compact concepts are used or developed, the more the design is ready.

Preliminary proposition for aimed tool

Taking into account the outcomes of explorative study, a process of reasoning, synthesizing and a continued evaluative leap (trial & error) to supposed criteria, results in a preliminary proposition. A knowledge structure is believed to be suitable for aimed generic methodological framework. This design supporting structure can be implemented in a cyclical or linear process of design, for random referencing, backgrounding, inspiration, ideation, and/or for selecting final solutions in whole or in part. The actual deployment of the structure depends on the preferences and level of expertise of the user.

A full description of the proposed knowledge structure is not possible within the limited length of this paper. A detailed and illustrated discussion will be the focus of the oral presentation.

The general outline of the framework approaches a gradation from theory to practice, and from problem to solution.The framework consists of implicit and explicit elements, preceded by a backgrounding and followed by a synthesizing part. Implicit elements are incorporated in the structure and content, while explicit elements are recognizable and distinctive parts as such. Implicit elements are: best real-life practice backed, cross structure referencing, suitable representation techniques, database of knowledge, building of episodic knowledge, transcending the specific, no value judgement, non exhaustive display, combinability's, satisfying and optimizing. Explicit elements are given in figure 1.

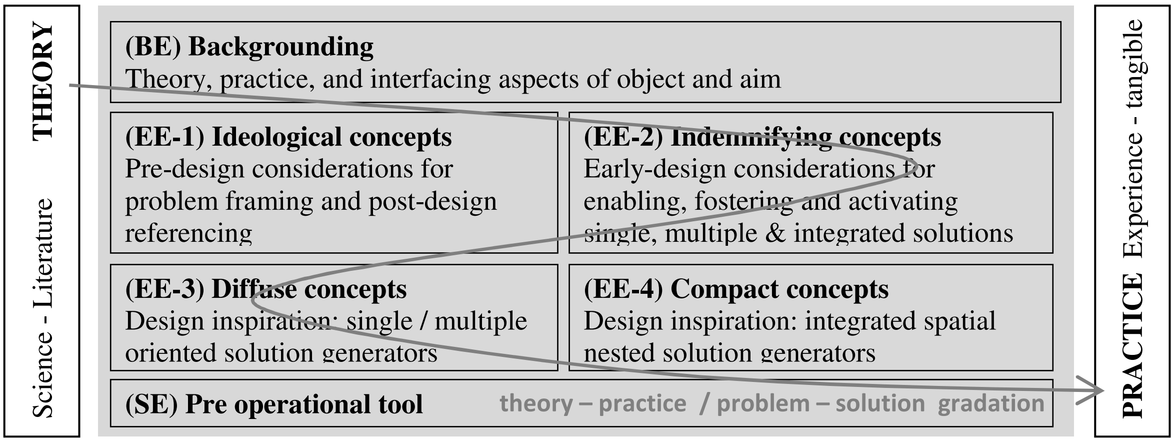

Figure 1 Explicit elements of preliminary proposed generic methodological framework.

FINALIZING REMARKS

Developing a tool, within the sustainability quest for the built environment specifically tailored for architect-designers, is an innovative but complex task. Tentative building and display of proposed framework in this paper must be seen as an incentive for discussion and further research. Experts in this field and related aspects are well placed for verification, adjusting and a further development.

The perspectives at short term are twofold. First, this research will be supplemented with a verification. Preliminary outcomes are to be presented to a selection of practicing architect-designers after which they will be asked to provide feedback. Second, in order to test the feasibility of aimed content of the tool, a specific substantive body of knowledge will be investigated and integrated in the framework. Both perspectives enable an evaluative loop of verification and adjustments, leading to improvements. During this process it is important to constantly safeguard developed and adjusted criteria, and to prevent relapsing in issues of current sustainability tools.

The preliminary result of this exploratory study is a confirmation of the hypothesis that prevailing up front kinds of sustainability tools are inadequate for architect-designers. Suggested generic methodological framework is seen as a possibility for the development of an operational sustainability tool specifically tailored for architect-designers.

ABSTRACT

In Nov. 2013, a hotel was completed beside the Biwa-lake in Moriyama city, Shiga Prefecture, Japan. This is a three storeyed building with 14 guest rooms. The main structure is reinforced concrete but the rammed earth walls were built as the partitions between guest rooms. The rammed earth, which was made from local and natural soil, was expected to work as a thermal mass for passive cooling in the summer time. Each hotel guest rooms faces to the west and has a good view of the lake. In this area, the prevailing wind in the summer time was west-east, and the ventilation cooling, utilizing this wind was planned. The design of this building was studied based on the results of simulation studies and it was expected to reduce 75% of cooling load. This paper discussed; 1) the design process of this building, 2) the results of simulation studies, 3) the performance of the ventilation cooling effects.

1. INTRODUCTIONAND BACKGROUND

Building low environmental impact architecture, throughout the life cycle, is a form of construction required for the coming years.When you build a building, making buildings that used local natural resources of the land, as much as possible,is the new imperative. Production of soil wall is known for its lesser environmental load or energy consumption than reinforced concrete. Rammed-earth,which is made by pressing soil inside frames, has a beautiful layered texture and humidity conditioning, and large thermal capacity. Then, we can use this wall, indoors, as a thermal mass to reduce heating and cooling load. In the former investigation we made experimental building with rammed earth in Kobe, then simulated and measured the thermal performance of the building. We presented how to use the rammed earth as thermal mass in the area.

In Nov. 2013, a hotel was completed beside the Biwa-lake in Moriyama city, Shiga Prefecture, Japan by Architects Ryuich Ashizawa Architect & Associates, and Soil-wall consultants, Kumiko Hatanaka design office, as shown in **Figure 1(a)**. This hotel has 3 rammed earth partition walls, as shown in **Figure 1(b)**. The authors investigated with the former method how many cooling load this rammed earth reduced. Furthermore, for more effectiveness, the effect of passive cooling by outside air intake was subjected to ventilation simulation in order to determine the opening position.

Figure 1 a) West face of the hotel seen from the lake. A music hall is on the left side of the hotel, b) The guestroom on the right wall is a rammed earth.

2. DESCRIPTION OF THE ARCHITECTURE

The hotel has three stories with fourteen guest rooms, one restaurant and one banquet room. The hotel has a wide view to the lake in the west. The Music hall that is used mainly for wedding ceremony is on the north to the hotel. The walls of the guest rooms are built with reinforced concrete except one. The floors are made by raised wood. Rammed earth walls are used as partition for rooms.The room has a rammed earth wall in the north or south. The windows are designed to ventilate from the west, the lakeside to the east, as shown in **Figure 2(a) & 2(b)**.

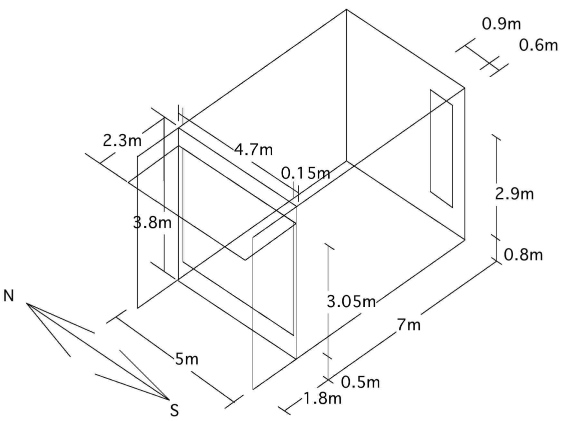
3. SIMULATION FOR THERMAL PERFORMANCE IN SUMMER (GUEST ROOM)

3-1. Simulation Model and Method

Although the forms of 14 guest rooms are varied, we computed the cooling load of “Room 4”,as shown in Figure 2(b), in the summer as a typical room. The room is twenty two square meters wide. The plan and elevation is distorted. The room is four metre wide on the west side. Although there is a bathroom and a closet in the east, for the simulation we assumed it simple form regardless of the parts. **Figure 3(a) & 3(b)** shows common details of the shape and specifications of room to simulate. We show the result of simulation on next page. On these information shown below, we varied materials of thermal mass.

The room was considered to be 4m wide, 4m deep, and 2.5m high. The opening of terrace side is made with double glazing in wooden frame. The wall thickness of guest room is 250mm, so we simulated considering that there are no heating affect by the next room which shares the wall as well as upper or lower rooms. Therefore, other than the west face, a glass wool of 500 mm thick on the outside of the Thermal mass was considered. We set 2.3m depth eave which is positioned over the terrace and 1.8m length on the sidewall of the terrace. As internal heat, we set 210J/h from refrigerator constantly, and 882J/h from two hotel guests who stay between 17p.m. and 8a.m. in the guestroom. We assumed that during the night time, between 18p.m. and 7a.m. a curtain would be closed as a night insulated door and when the outdoor temperature is between 18- 26 ºC, the outdoor air inlet would be open. In this case, simulation model is Room 4, which is call “Real model”. There is a rammed earth wall at north side wall. The floor was covered with a wooden floorboard. The west side have big window. The walls of guest rooms are built with reinforced concrete except one, as shown in **Figure 3(a) & 3(b)**. The thermal mass material is changed, and what kind of cooling load, was calculated according to the flow diagram, as shown in **Figure 4(a)**. Material constituting the respective models, are as shown in **Figure 4(b)**. Material properties are, as shown in **Figure 4(c)**. We simulated the thermal performance with the design tool “Solar Designer ver.6” developed by the authors.



form		width 5 × depth 7 × hight 3.8(m) raised floor

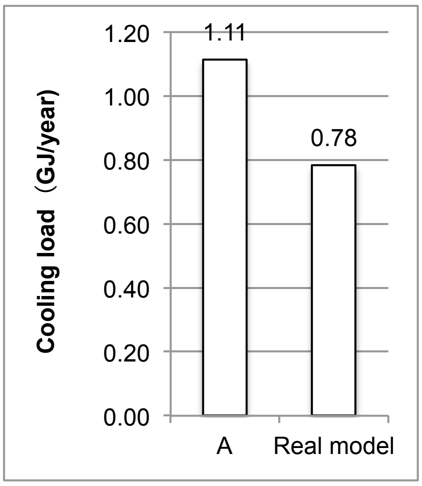
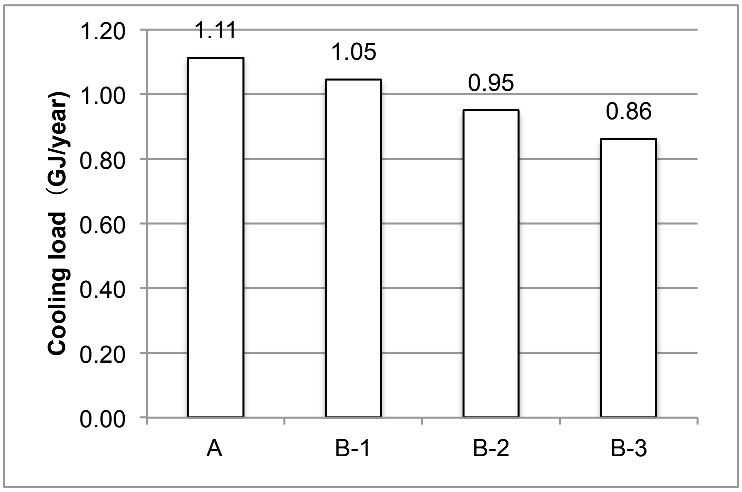
3-2. Thermal performance in summer

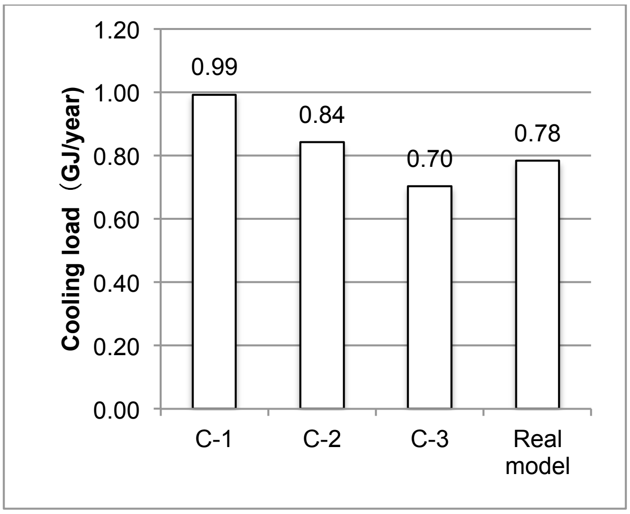


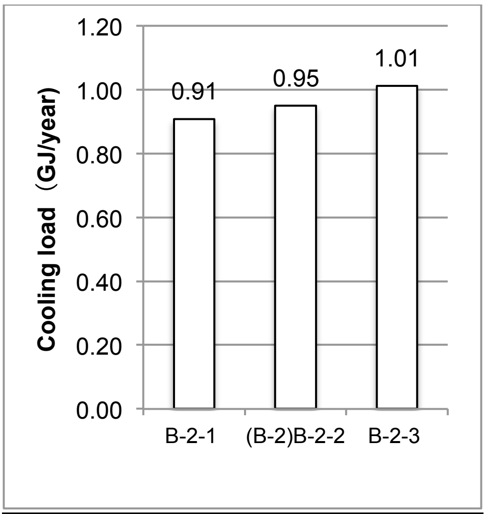


a) Model types A & Real model b) Model types A & B

Figure 5 a) Annual cooling load for A & Real model, and b) Annual cooling load for A & B types

Figure 5(a) shows the comparison of the cooling load for "model A", made in wood (plywood),as shown in **Figure 4(a), 4(b), 4(c)**, with the "Real model", as shown in **Figure 2(b)**. Rammed earth thermal mass walls are expected to work well for the cooling load. B-1 has a rammed earth wall in the north side, and the rest of the walls of the guest room is built with wood, as shown in **Figure 4(a), 4(b) & 4(c)**. B-2 has 3 rammed earth walls. B-3 has 5 rammed earthwalls, as shown in **Figure 4(a), 4(b) & 4(c)**. The analysis shows that the cooling load decreases with increase in rammed earth walls, as shown in **Figure 5(b)**. **Figure 6(a)** shows thermal mass works well for the cooling load. C-1 has one reinforced concrete wall in north side and the other walls are built with wood, C-2 has 3 RC walls, C-3 has 5 RC walls, as shown in **Figure 4(a), 4(b) & 4(c)**. In this case also, the cooling load decreases as the amount of RC walls increase, as shown in **Figure 6(a)**. **Figure 6(a)** shows comparison of cooling load for "Real model", which has wooden floor and one rammed earth wall. So, it has less thermal mass and a little bigger cooling load than C-3. But "Real Model" has less cooling load than C-2.





Material	Thermal conductivity (W/m・K)	Specific heat capacity (kJ/m3K)
B−2−1 Dense rammed earth	0.70	1381
(B−2)B−2−2Middle dense Rammed earth	0.58	1130
B−2−3 Rough rammed earth	0.47	837

a) Model C-types & Real model b) Model B-types comparison and material properties

Figure 6 a) Annual cooling load for C types & Real model, b) Annual cooling load for B types and Thermal conductivity and specific heat capacity of rammed earth with various density.

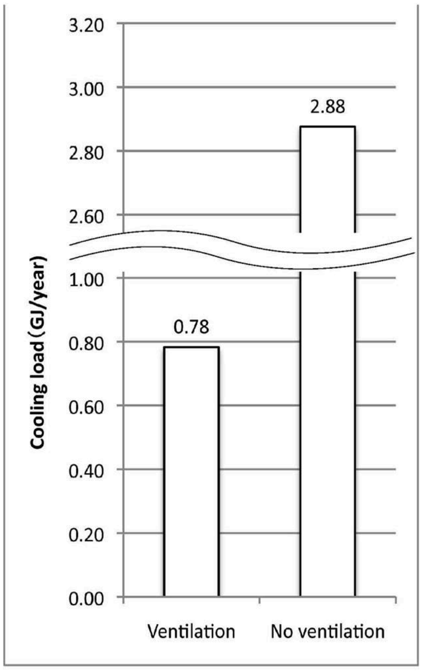


Figure 7 Annual cooling load / Ventilation mode and no ventilation mode

Rammed earth has various conditions determined by what the type of soil used, and how hard the earth was rammed. So,we considered three different thermal conductivity and volumetric specific heat of rammed earth: Rammed earth 1 is high density; Rammed earth 2 is mid density; Rammed earth 3 is rough, low density. **Figure 6(b)** shows that as the density of the rammed earth increases, the cooling load is lower. The cooling load comparison of the cases shows that in the dense version built, the cooling load is reduced. In case of the "Real model" the cooling load decrease, if we compare to **C-1 & C-2** modes. When only active cooling is used windows are closed and air change rate of 0.5 times per hour is considered, and when the outdoor temperature range is 18~26ºC, 15 ACH, natural ventilation is used. The simulation results of 3 ways using,ventilation mode and non-ventilation mode, and cooling load is reduced by 75% in ventilation mode, as shown in **Figure 7**.

3-3. Conclusion

This examination shows ventilation is effective to be used in the guest room to reduce the cooling load. And Rammed earth is an effective material to reduce cooling load and embodied energy. Then, rammed earth is the next generation's material. And,the simulation is an effective tool for verification of the same.

4. DESIGN OF THE WINDOW (GUEST ROOM)

4-1 Simulation Model and Method

The thermal environment simulation, showed cooling load reduction and the ventilation cooling effects obtained by taking advantage of the heat storage of the rammed-earth wall. Night ventilation takes in the cold air of the night, and stores it until the next day. For this purpose, it is necessary to ventilate an appropriate amount while considering appropriate security and privacy. In this section, we describe the design of the opening to ensure a desired flow distribution and airflow, and introduce the simulation results of the flow.

Western windward side is a picture window to capture the views of Lake Biwa. In order to retain the view, a window for ventilation was provided for at the position of the feet.The louver door installed at the east entrance leeward location was designed to allow wind flow, and through the common corridor, as shown in **Figure 8(a) & 8(b)**.Under these conditions, we investigated the air volume flow and felt the wind present at the guest locations. We simulated the wind flow with "STREAM".

4-2 Study of the wind flow

Study of the relative positions of the inlet and the outlet are, as shown in **Figure 8(a) & 8(b)**. In Model 1, a window is arranged at a position frontally facing the entrance, and in Model 2, the window is arranged in a position diagonal to the entrance, as shown in **Figure 8(a) & 8(b)**. In view of the locations of residents and placement of furniture, we decided to model-1 wind flow in a region where there is a bench in front of the bed, as shown in **Figure 8(a) & 8(b)**.

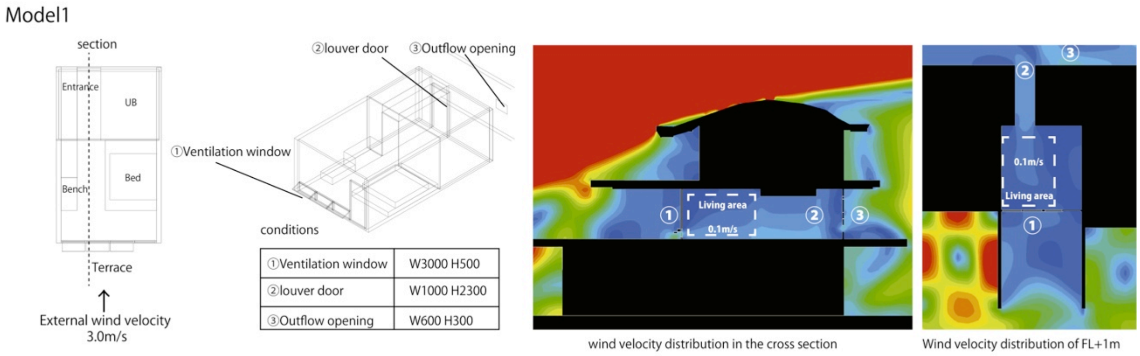

Figure 8 (a) Window layout for Model-1

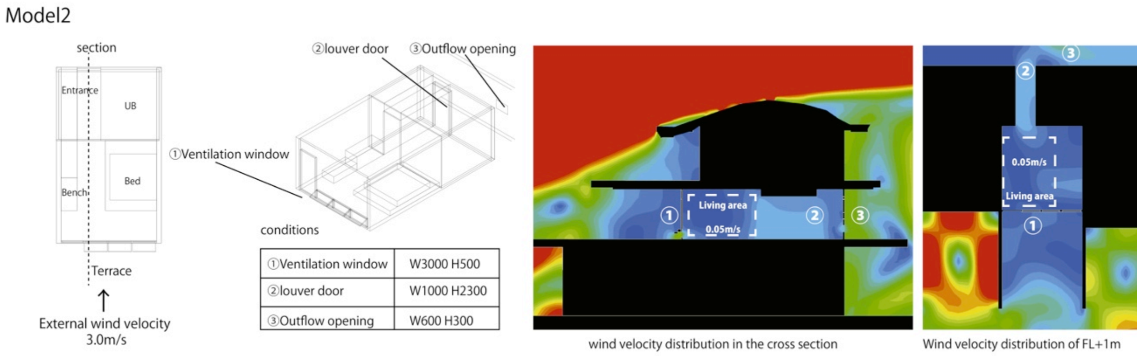

Figure 8 (b) Window layout for Model-2

4-3 Study of the amount of air

In order to easily adjust the air flow, the position and size of the opening of the common corridor was changed, as shown in **Figure 9**. Model 3, as shown in **Figure 9,** is a view after the change. Originally, a window was placed near the ceiling of the front of the entrance door that had been placed randomly, and took larger opening area. As a result of the reconfigured scheme, the wind went from the foot opening, and goes out of the high window, and air volume is increased than Model 1.

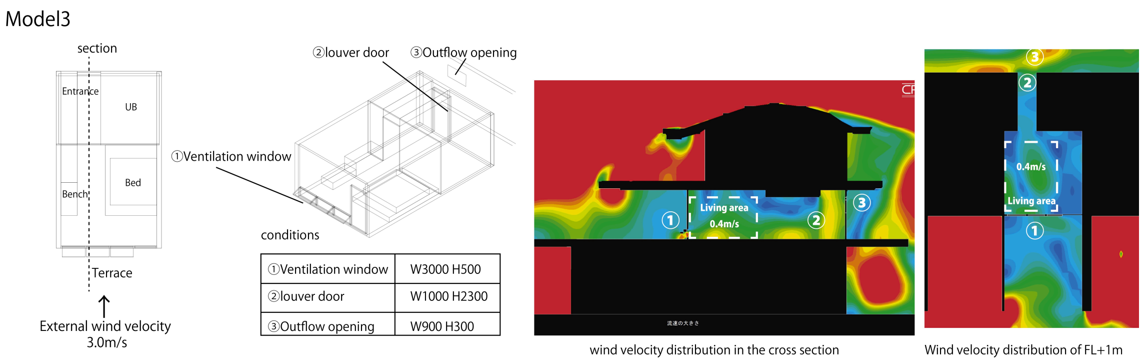

Figure 9 Windows layout for Model-3

4-4 Conclusion

In order to enable the guest to adjust and incorporate their own style, the authors consider how to open the window and placement of the opening, and were able to ensure proper ventilation and air-flow path.

5. CONCLUSION

The building design, based on the above studies, was completed and is currently in operation. The authors consider making comparison between the actual measured value and actual simulations, responsive user praxis of opening the window to introduce outside air, and the feel and experience of hotel guests through questionaire, and the mechanisms of outside air intake. Furthermore, our objective is to advise the hotel management on the low energy practices.

ABSTRACT

Jali Screens are traditional window treatments used in vernacular buildings throughout South Asia and the Middle East. Historically, the screen treatments are successful in providing shade and privacy for building occupants in hot arid and hot humid climates. With interest in traditional building features, recent trends in contemporary buildings design have started to incorporate Jali screens or other screens as decorative façade elements. However, the use of these screens has been widely approached from the aesthetic and romantic attitude representing an architectural fascination with the vernacular. Their impact on overall building energy and daylighting performance, however, has been largely ignored. This paper reports on the results of a multi-methods research project to evaluate the impact of traditional Jali screens with various perforation ratios on energy utilization and daylighting quality in contemporary office buildings in Lahore, Pakistan. The study combined a field assessment of traditional Jali screen performance in historical settings with various geometries and an experimental simulation of the different screen perforations on contemporary offices' energy behavior and daylighting autonomy. The hypothesis studied is that Jali screens with 30%-50% perforations will provide an optimized condition between energy savings and daylighting quality in office buildings. Independent variables including building envelope insulation, shading factor, and perforation percentages of Jali screens were manipulated through different simulation models of an existing office building. The dependent variables in the form of overall energy utilization intensity (kbtu/sf/yr), daylighting autonomy, and annual solar exposure were analysed for the different screen attributes. Simulations, using computational energy modeling, have revealed that Jali screens impact cooling loads and improve visual comfort in office buildings. Moreover, it suggests that designers should look at traditional building strategies from a holistic perspective employing a whole-building approach including aesthetics and an intent to quantify its performance and learn from it without over-romanticizing it.

INTRODUCTION

Lahore, a modern financial center in Pakistan, is dominated with office buildings. These offices are air-conditioned throughout the year. In Pakistan, the current energy crisis makes evaluating building performance an urgent need in design practice. The climate of Lahore is typically characterized by a high intensity of solar radiation. Solar heat gain reduction is of primary concern as a means to reduce energy use and provide comfort to occupants in warm weather (Boake, 2014).

Unprotected glass curtain walls are not very climate friendly in warm and hot-humid Lahore. Typically occupants use blinds on the inside of the window to control glare only, while significantly increasing the total building energy when compared to external shading devices (Moeck et al.). Prior research based on the Lahore region did not use the weather data for Lahore, instead similar climate data was used to draw relevant conclusions. Figure 1 shows a psychrometric chart for Lahore, Pakistan (Source: Climate Consultant 5.5 (B1). While the climate of Lahore is such that comfort is only achieved 15% of the time; an additional 24% comfort time can be achieved through sun protection or shading of windows alone.

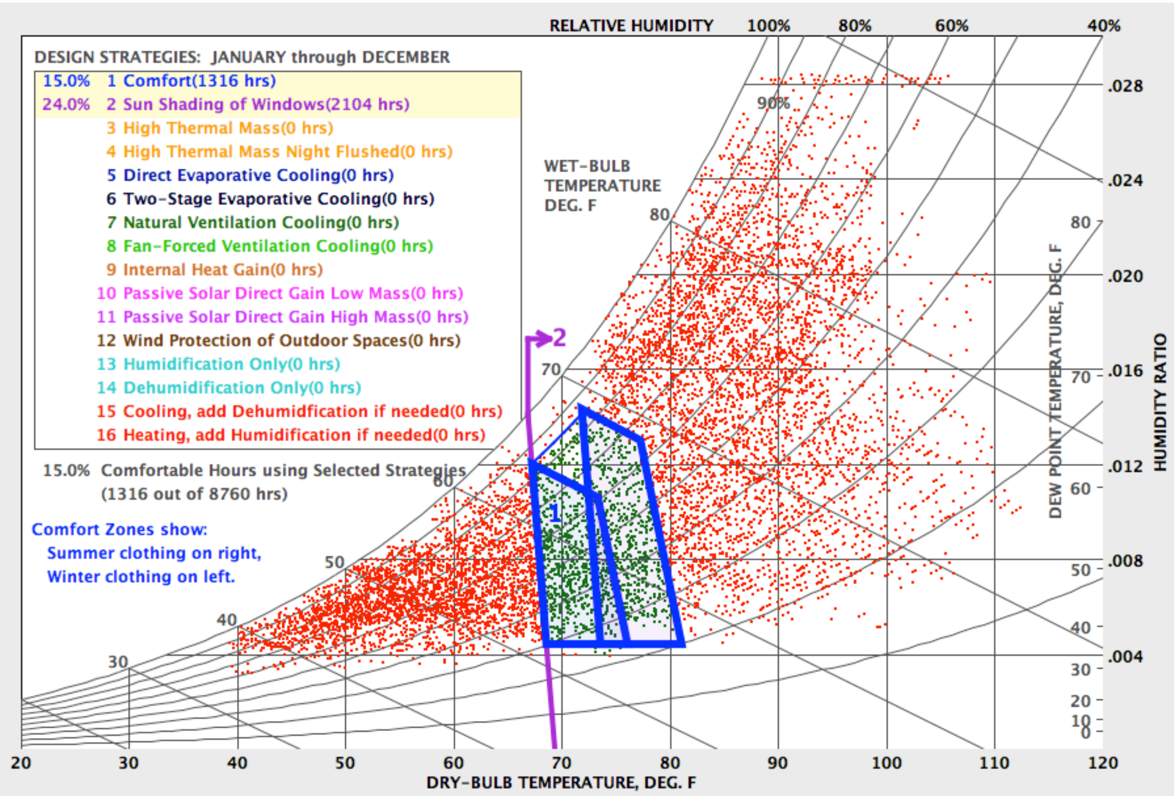

Figure 1. Psychrometric Chart for Lahore, Pakistan (using ASHRAE Handbook of Fundamentals Comfort Model, 2005)

Certain envelope-design strategies have already proved to serve the purpose of energy saving in buildings (Olgyay et al., 1957; Dekay et al., 2014). There are several prescriptive sets of building criteria available to attain the thermal and comfort benefits, and ASHRAE has published several of them (Zhivov et al., 2010). However, such standards pertaining to thermal comfort are not available in Pakistan and the thermal properties of building construction in buildings are very poor. Single glazed curtain wall systems with low thermal resistance envelope designs are still prevalent. A few buildings in the Gulf area and in Pakistan have performance claims, which are not backed by any hard numerical evidence (Boake, 2014).

Jali screen façades have been widely used as vernacular shading devices in the Pakistan, India and Middle Eastern countries. Previous studies have proved their climatic adaptation and environmental performance (Elzeyadi, 1996). Jali, in Urdu language, means a perforation or perforated screen. Over the years, architects and builders have acknowledged its benefits as a screen that filters light and air, while allowing selective privacy. Traditional Jali facades are replicated and used in contemporary buildings in Lahore, Pakistan. However, there is a lack in understanding of their performances in a quantitative manner and unavailability of scientific means that could be used for developing new efficient designs that suit the modern façades of office buildings in Lahore. Figure 2, shows an example of a contemporary building in Lahore where Jali facades are used as ornament and daylight is blocked out. Fathy (1986) indicated that perforated screens, for example Mashrabiya in Egypt (Fig. 3) affect the quality of space and improve visual comfort in spaces by reducing glare. Several studies show that external screens reduce solar penetration as solar radiation is rejected before hitting the glazing (IESNA Lighting Handbook 2013; Kwok et al., 2011). The hypothesis of this study was that Jali Facades in Lahore would help achieve thermal comfort and as well as improve daylighting performance in office environments.

Figure 2. Mall of Lahore (left) is a commercial building with ornamental Jali Facades, Lahore (Source: author); Figure 3. The House of Suhaymi (right) in Cairo, with one of the Mashrabiyas, Egypt (Source: Wikipedia accessed on September 16, 2014).

Research Setting - Traditional vs. Contemporary

Three Jali screens were selected from typical vernacular architecture of Lahore. The Lahore Fort has the largest collection of Jali screens in place from the Mughal times (16^{th} to 19^{th} century). All three cases selected for investigation are west facing with a perfortation ratio of 30%, 40% and 50%. Perforation ratio, for this study, is defined as the ratio of void to solid area of a screen. The depth of screen was fairly constant at 0.25’ (3 inches) and after an analysis of screen geometry (Fig. 6) the depth to width ratio of 1:1 was taken as most commonly occurring.

A typical office building was selected to act as the contemporary research setting. This base case building was located in the Commercial Area of Y-Block, Defence Housing Society in Lahore, Pakistan. This building is at the corner junction of two main roads with facades facing South and West composed of single pane unprotected glazing. It consists of 5 floors including Basement, Ground, Mezzanine, First, and Second typical floors (Fig. 4). For detailed daylighting analysis two rooms on the Second floor are selected as shown in Figure 4. Information on building characteristics such as location, orientation, environmental factors, envelope characteristics, installation systems, comfort ranges, schedules, and occupancy were gathered (Caccavelli, 2000; Butala, 1999; Gücyeter et al., 2012). A total building energy audit was acquired for the whole year and readings for daylighting measurements were taken at a 3’ (three feet) grid on working plane for the two offices at morning and afternoon time, on a typical sunny day in April.

RESEARCH METHODS

The impact of Jali screens on energy conservation and visual comfort of typical contemporary office buildings in Lahore, Pakistan formed the core of this investigation. Details of variables, which affect the energy of building, cooling and lighting, were identified and formed the sub-questions of the study and a review of the literature. The results from the field study impacted decisions taken during the experimental design stage. Figure 5 describes the parameters used in the experimental desgn stage. In order to simulate conditions accurately, this research employs dynamic energy simulation, starting with a building audit of the existing base case scenario, which was then fed into the simulation model to assess existing performance levels and create a calibrated model. Figure 5 shows the flow of methods employed for this research.

Figure 4. Contemporary Research Setting: West Façade (left); South façade (right).

Computational and environmental simulation software, IES Virtual Environment Pro (IES_VE), program used in this experimental research (Kim et al., 2012) and has been verified in many publications (The American Institute of Architects, 2012; Elzeyadi, 2009). Only four modules of the package were used to carry out this investigation, which are “ModelIT”, “SunCast” for solar shading analysis, “Radiance” for dynamic lighting simulation and “Apache Sim” for thermal simulation (Muhaisen, 2006; Aldossary, 2014).

Next, Jali screens defined from the traditional research setting (traditional building cases) and designed for this experiment were tested through the calibrated model. The calibrated model was further validated with Target finder and the EUI values in the base case were found to be too high for a balanced experiment. High performance thermal constructions were employed and verified as having a significant impact on performance. Furthermore, all shading devices were based on the optimized base case model (Fig. 5).

Envelope design in Lahore is very leaky and has low R-value. High performance buildings require not only good shading design but also thermal constructions with higher R-values. Research has shown that with bad thermal construction and leaky envelopes, shading devices cannot achieve the same effect as a good thermal construction (Sourced from GCT High Performance Template) (Elzeyadi, 2008). High performance materials were used for further final simulation for testing all shading devices (Table 1).

Table 1. High Performance Thermal Constructions used in Simulation Model

Roof	High Performance Roof [R40]
External Wall	High Performance Wall [R-30]
External Glazing	Low-e Triple Glazed [R-5]
Ground Floor	Super Insulated Floor [R-25]

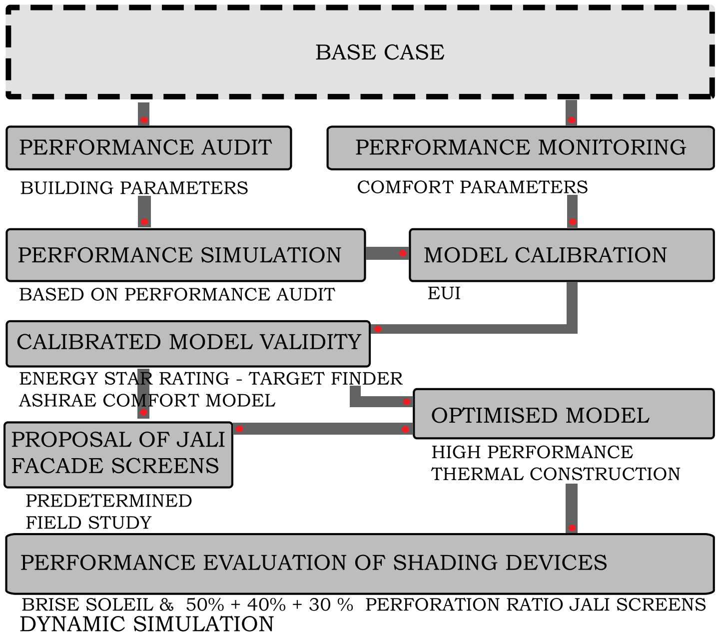

Figure 5. Flow Chart of Performance Monitoring, Calibration and Optimization

Further optimization was achieved through the use of dimming profile for lighting controls (High performance Template) (Elzeyadi, 2008). According to this template, a value of 360 lux was set on the work surface to optimize lighting controls such that maximum utilization of daylighting was achieved and electric lighting minimized during an ASHRAE work day of 8:00 am till 6:00 pm. Figure 5 shows the process through which the simulation model was calibrated and optimized to achieve the best results for assessment of Jali screen façades.

Jali patterns were investigated and derived in the traditional research settings. It was found that most shapes were derived from a hexagon in the Jali screens (Fig. 6). In order to simplify the process, therefore, basic shape of a hexagon was selected for the purpose of experiment. To find a screen configuration of highest energy saving potential, a range of solar screen designs was examined by performing computer simulation using IES VE dynamic simulation software.

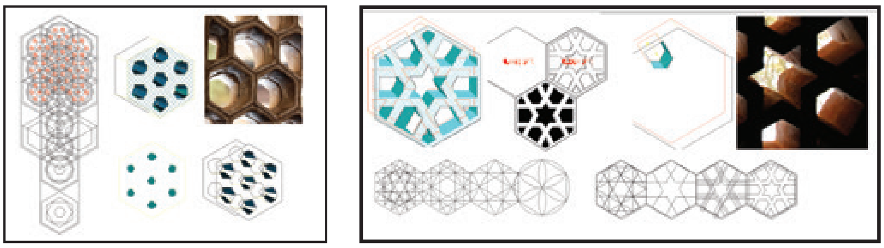

Figure 6. Jali Geometry Detail

ANALYSIS

Energy Performance and Thermal Comfort

Initial data collection from base case contemporary building indicated that the temperatures were out of comfort range. Both diagrams (Fig. 7) show how the temperature recorded in the study rooms was found to be out of the comfort zone defined by ASHRAE 2005 Comfort Model (Climate Consultant 5.5 B1) and Center for the Built Environment: CBE Thermal Comfort Tool.

To account for building energy consumption, Energy Utilization Index (EUI) was used to compare the energy benchmarking of building and design strategies. Mean EUI of commercial buildings in the US was calculated from Target Finder and used to compare with the base case EUI in Lahore (Fig. 8). EPA's online Target Finder Calculator (EnergyStar) was used to find the base case building Site EUI for a similar climate zone in the US. Target finder US Base case was 77 kBtu/ft^2/yr and the value of existing building is calculated at 254 kBtu/ft^2/yr.

The base case contemporary building was then modeled with the existing construction techniques in the building as built in Lahore, Pakistan. The results of this simulation showed a high value of 80.3 kBtu/ft^2/yr. When using better construction, i.e., using GCT High Performance template, as shown in Table 1, studies have shown significant impact on the energy performance of buildings (Elzeyadi, 2008). Introducing better thermal construction reduced the EUI to 67.68 kBtu/ft^2/yr. Furthermore; the existing conditions of base case were not optimized for lighting and solar gain. By introducing a dimming profile of ASHRAE 8:00 am – 6:00 pm workday, the EUI was further reduced to 55.01 kBtu/ft^2/yr (Figure 9).

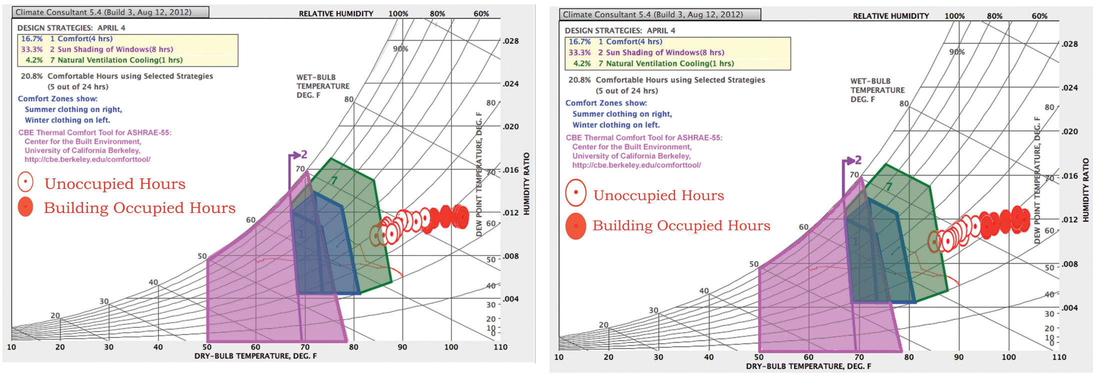

Figure 7. Psychrometric Chart (South - left) (West - right)

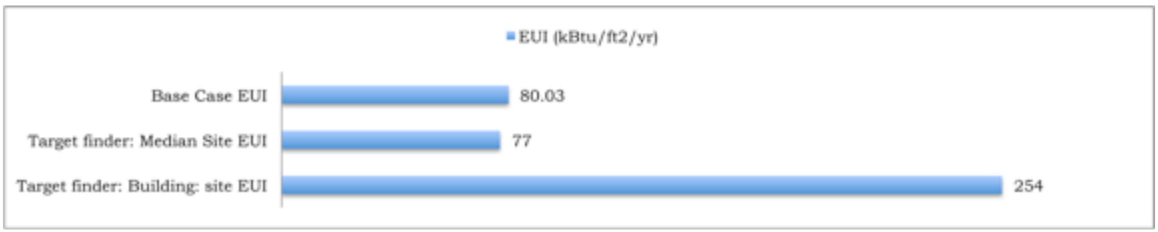

Figure 8. Building EUI comparison with Energy Star Rating

External shading devices, three types of Jali screens, were then added to this computational building model. As shown in Figure 10, EUI improved with perforation ratio of 30% to 50%, with 50% Jali perforation screen as the best performer due to combination of solar heat reduction and daylighting potential.

Figure 9. EUI Values derived through Dynamic Simulation Modelling

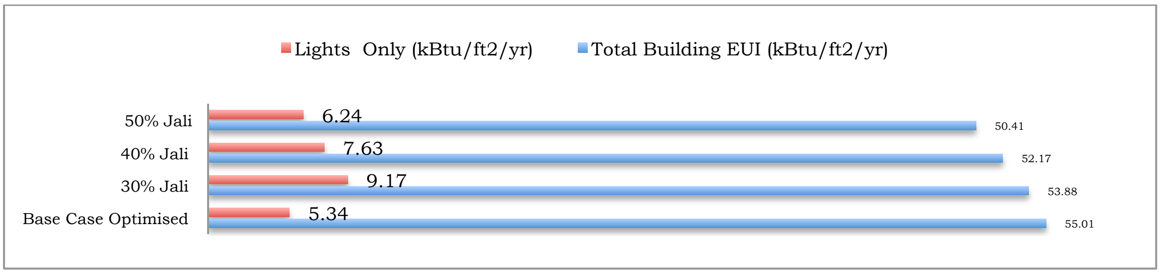

Figure 10. Comparison of Lights Energy and Total Building EUI

Daylight Performance

Experiments for the previous simulations were conducted in Radiance module of IES VE dynamic simulation software. The times of the day were set to the 8:00 am to 6:00 pm workday, per IES standard a given preset in IES VE dynamic simulation software. The reference plane on which daylighting performance was simulated contained sensors at a height of three feet above floor (working plane). Dynamic daylight performance metrics were used to assess the illuminance ratios within the rooms. These simulations extended over the whole calendar year and were based on external, annual solar radiation data for the building site. The key advantage of "dynamic daylight performance metrics compared to static metrics is that they consider the quantity and character of climate and seasonal variations of daylight for a given building site together with irregular meteorological events" (Reinhart et al. 2006). Two metrics used in this research were Spatial Daylight Autonomy (sDA) and Annual Sunlight Exposure (ASE) both defined by IESNA (IESNA Lighting Handbook) and found most suited for assessing daylighting quality in an office environment and solar penetration through the Jali screens.

South Orientation

When assessing through the Spatial Daylight Autonomy (sDA) metric, all shading strategies fulfilled the criteria of being 100% as shown in Figure 10 (Green – pass; red – no pass). There was sufficient daylighting to fulfill the minimum daylighting criteria. However, Annual Sunlight Exposure metric was not fulfilled barely towards the back of the room in 30% Jali perforation ratio. It is predictable due to the lesser lighter penetrating deeper on South. This indicated further shading in the deeper parts of the building.

West Orientation

In the west room, the Spatial Daylight Autonomy (sDA) could not be achieved in lower perforation ratios. For the optimum lighting requirement, dependence on electrical lighting increased, while impacting lighting energy (Fig. 10). Similarly in Annual Sunlight Exposure metric, 50% Jali perforation received maximum amount of direct beams of sunlight in comparison to lower perforation ratios (Fig.

11).

Discussion

Energy was measured and assessed in the EUI metric (Fig. 9 & Fig. 10). The thermal construction of a building had a large impact on its energy performance. This study showed that by optimizing the thermal construction using Green Class Toolbox (Elzeyadi, 2008) high total energy savings were made possible. Earlier, it had been discovered during field research, that thermal consrtuctions of buildings in Lahore is not up to ASHRAE standard. Installing standardized construction by using thermal and vapour barriers in building envelope should dramatically improve performance of buildings (Fig. 9). Solar shading devices on windows are significant components of vernacular building façades in Lahore, Pakistan. This research showed (Fig. 10) how each of the three Jali screen façades affected the total energy of the building. Out of the three screen geometries, it can be concluded from this study that the 50% perforation ratio performed best (1:1 perforation to depth). As the perforation ratio was increased from 30% to 50% whole building energy performance improved due to decreased reliance on on electrical lighting for daylighting (Fig. 10 & Fig. 11). In comparison, 50% Jali perforation was the better option for a balanced energy approach to provide thermal comfort and provide optimum daylighting. The impact of Jali screen geometry on energy performance is significant to suggest that designers may use this research to improve thermal visual comfort in contemporary buildings and reduce depence on electricity.

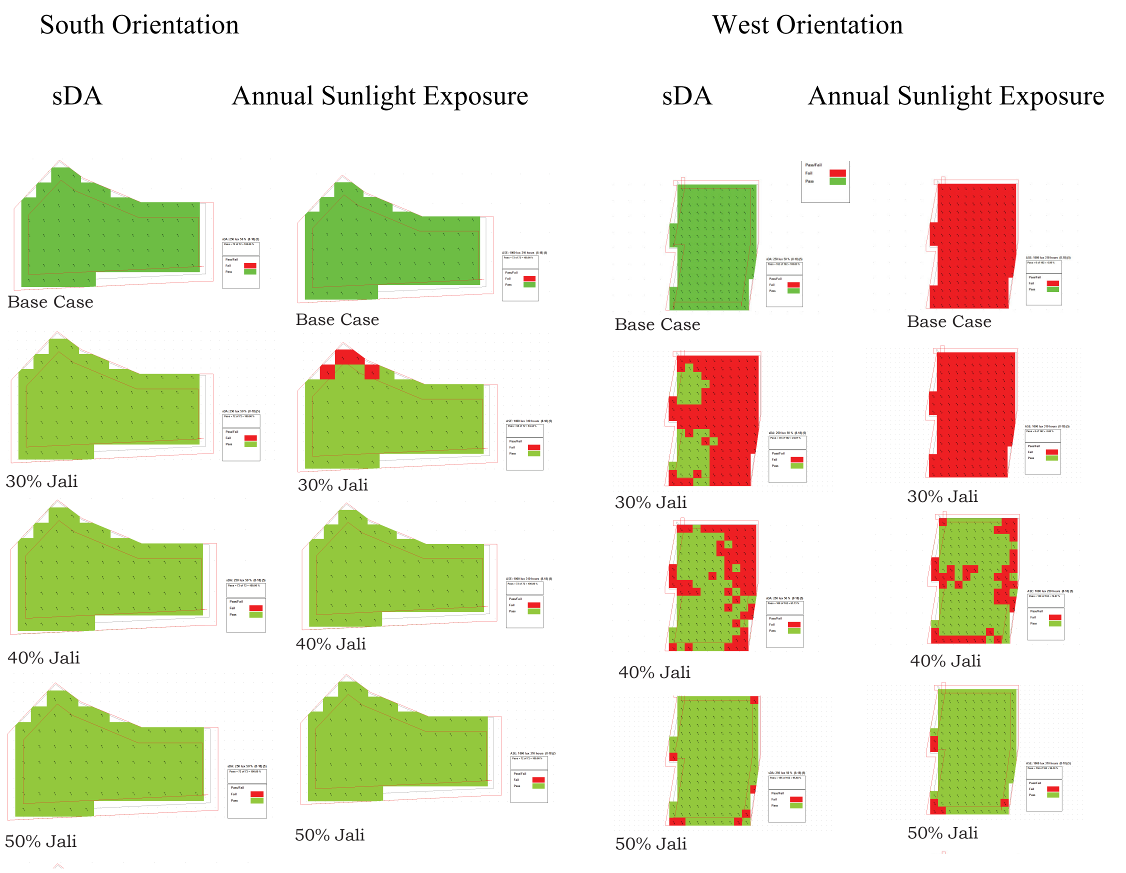

Figure 11. South Orientation (left) Spatial Daylight Autonomy: (left) and . Annual Sunlight Exposure (right); West Orientation (right) Spatial Daylight Autonomy: (left) and . Annual Sunlight Exposure (right).

CONCLUSION

This research examined the effect of Jali Screen façades on the year round energy performance and daylight performance through a dynamic simulation model. The conclusion is focused on the impact of shading devices beyond the aesthetic application; in particular, the geometry of Jali screens façades on Energy Saving and Daylighting Performance in contemporary office spaces in Lahore, Pakistan. For each of the two orientations, South and West, three Jali screens were designed and simulated. In order to draw a conclusion from this study, a holistic approach towards cooling and lighting energy is required, using a whole building design approach. While implementating Jali screens in contemporary façades, designers may seek aesthetic quality along with thermal and visual comfort. Masterbuilders had embedded this information in the various screens found in the traditional architecture of Pakistan, especially Lahore, and we can re-learn from these façade systems to develop a high-performance building design. Jali screens can be optimized for beauty and performance given the parameters are carefully designed.

ABSTRACT

The design of a solar protection system that can minimize solar gains while maximizing daylight and view to the outside is particularly challenging in arid climates, such as in the Middle-East, where sand, wind and corrosion impose specific constraints. We propose a system that provides a trade-off for three requirements: (i) maximize diffuse sunlight and view to the outside, (ii) efficiently block direct sunlight and (iii) transform a fraction of it into diffuse light for indoor daylighting. Compliance with this last requirement provides a solution for the common problem of insufficient daylighting even in the presence of abundant solar radiation, which often forces occupants to fully close their shading system and use electric lighting. In addition, our design potentially copes well with these extreme environmental conditions and preserves local architectural character (mashrabiya-inspired design). In this paper, we establish quantitative specifications for these three requirements, provide the working principle of our shading and daylighting system and its design, which consists of a shape variable mashrabiya (SVM). We calculate and analyze the annual daylighting performance of our SVM and benchmark it against the performance of Venetian blinds and diffuse sunlight alone. Finally, we provide the minimum reflectance required for the SVM to comply with our third requirement. We built a mock-up of our SVM to investigate the validity of our simulation model.

INTRODUCTION

The abundance of solar radiation in arid regions like in the Middle-East requires a very efficient shading system, in particular when aiming to provide visual comfort and prevent excessive solar gains. In addition, the combination of sand, wind and corrosion due to prevalent condensation creates harsh environmental constraints. On the one hand, the static vernacular solution named mashrabiya (perforated shield with oriental motifs) is well adapted to these constraints but fails to meet our contemporary needs for visual comfort due to insufficient daylighting and view to the outside. On the other hand, a kinetic shading system like Venetian blinds meets the requirements for efficient shading and for visual comfort (minimal glare, adequate daylighting and maximum view to the outside). However, to avoid excessive solar gains, such a shading system must be placed outside of the window, where it cannot withstand the harsh local environmental conditions. More sophisticated contemporary technologies embedded in the window, like electrochromic glass, are in principle unsuitable for these climates due to their propensity to absorb solar radiation resulting in excessive solar gains. Therefore, the challenge is to design a kinetic shading system that can cope with these harsh environmental conditions.

We propose a solution relying on a simple strategy to deal with abundant solar radiation that is applicable in these specific climatic conditions. With clear sky conditions prevailing throughout most of the year in these regions, strong direct sunlight on a window must be blocked without compromise. We believe that fine adjustments of the shading system with solar incidence angle are not strictly necessary, and not even desirable when striving to minimize solar gains. With this assumption, the shading system is closed in the presence of direct sunlight, and open when diffuse sunlight dominates. The sufficiency of such a binary function facilitates the design of a simple and robust kinetic shading system with the potential to cope with harsh climate conditions. Another important motivation for using a kinetic shading system with binary operation is the possibility to obtain a solar responsive system by exploiting a novel passive actuator. Applied as such, our approach would provide insufficient daylighting when blocking direct sunlight. This limitation, which is commonplace - independently of climatic conditions - in most shading systems, quite absurdly forces the occupants to use electric lighting despite abundant daylight availability. To tackle this, we devised a shading system that allows blocking direct sunlight while transforming a sufficient fraction of it into diffuse light for indoor daylighting. In addition to this key design-goal, we will devise a system that aims to preserve local architectural character.

In this paper, we provide the high-level requirements for this shading/daylighting system and explain its working principle. Then, we establish more detailed specifications and present the resulting design. We investigate the minimal reflectance required for the system to meet our daylighting goals and calculate annual daylighting performance. We close with a discussion of our results and benefits of this novel customized solar protection for arid climates.

SHADING AND DAYLIGHTING SYSTEM

High-level requirements

Our shading and daylighting system must comply with the following technological, functional, and architectural requirements: 1) ability to switch in a timely manner between an open and a closed configuration, in the absence and presence of direct sunlight, respectively; 2) maximal daylighting and view to the outside in the open configuration; 3) efficient shading and minimal solar gains in the closed configuration; 4) transformation of a sufficient fraction of the blocked incident direct sunlight into diffuse indoor daylight; 5) ability to withstand the harsh local climatic conditions; 6) potential for coupling our solar responsive system; 7) preservation of some local architectural character by using a mashrabiya-inspired design in both the open and close configurations. To reflect the above requirements, we will designate our system by “shape variable mashrabiya”, abbreviated SVM.

Concept and working principle

Our SVM is made of three identical perforated opaque shields that can move relative to each other to switch between an open and a closed configuration (**Figure 1**). A shield consists of a bi-dimensional assembly of identical perforated motifs, each covering a square area with side-length ℓ.

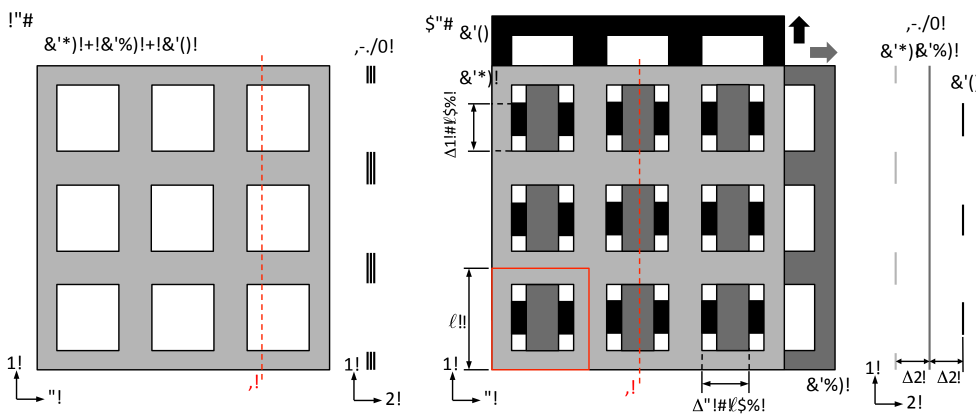

Figure 1 Concept and working principle of the SVM. (a) Open configuration. (b) Closed configuration.

The first shield is always motionless. In the open configuration (**Figure 1 (a)**), used when diffuse sunlight dominates, the shields are exactly superimposed and nearly in contact with each other. In the closed configuration (**Figure 1 (b)**), activated in the presence of direct sunlight, the second (S2) and third (S3) shields individually move along the vertical and lateral dimensions (x- and y-axis) by half of the motif length ($\ell/2$), respectively. Moreover, they both move in the z dimension to create a gap of length Δz between the shields, whose role is to allow multiple scattering reflections. As illustrated in **figure 2 (a)**), with an appropriate design, this results in the transformation of a significant fraction of direct sunlight into scattered light. Such a direct into diffuse light transformation (DDT) function must be optimized to obtain sufficient diffuse indoor daylighting.

To simultaneously move a shield along the lateral (x or y) and axial (z) dimensions, we devised a mechanism requiring few components and minimizing friction. It consists of a simple parallelepiped mechanical structure that allows switching between the two configurations by rotating the structure of an angle (γ), as depicted in **figure 2 (c)**. This structure allows simultaneously moving a whole assembly of mechanically interconnected shields from a single rotation point (P).

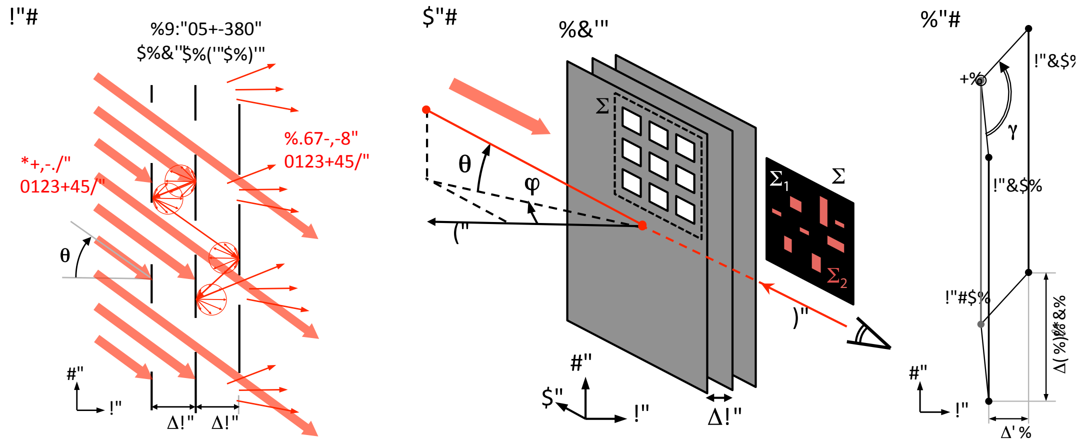

Figure 2 (a) Concept of the direct to diffuse light transformation (DDT) function. (b) Key geometrical parameters for defining the Shading Efficiency Factor (Γ), used in our specifications. (c) Mechanical concept for moving the SVM shields.

We plan to produce the required mechanical couple by means of a solar passive actuation and detection system based on a combination of custom optics and phase change material, which is currently being designed in our group. Such a solar responsive system, which is essentially restricted to binary actuation, lends itself well to moving our SVM. Since solar irradiation decreases with the cosine of incidence angle, solar gains are significantly reduced at elevation angles above 60°. Glare issues generally also become less critical in this angular range. Therefore, we designed our solar responsive system to switch from open to closed configuration at angles for $\theta < 60°$ and $|\varphi| < 60°$ (**Figure 2 (b)**).

The combination of such a simple solar responsive system (no detector, motor, electronics), whose description is outside of the scope of this paper, with this simple mechanical structure, is key to obtain a robust enough system potentially able to cope with the harsh local climatic conditions.

SPECIFICATIONS AND DESIGN OF OUR SHAPE VARIABLE MASHRABIYA (SVM)

Specifications

Shading. Specifications for shading depend on performance objectives, which are related to climate and to the usage of the space considered. Therefore, shading specifications are largely case-dependent. Here, we consider a public space (lobby, hall etc.) located in arid regions, for which glare and solar gains must be minimized. Such an objective can be formulated by means of a quantitative requirement on the maximum fraction of direct sunlight traversing the SVM structure. In the open configuration, since all three shields are superimposed, we simply need to specify the shading ratio (complement of the perforation ratio) of a shield of the SVM. Since, in the closed configuration, the shading ratio depends on the viewing direction (v), it is defined as: $\Sigma_1/\Sigma = (\Sigma_2 - \Sigma)/\Sigma$, where Σ_2 and Σ_1 are the illuminated and shaded surface portions of an area Σ (see **figure 2 (b)**). To establish a specification we need to introduce a more complex metric that accounts for this angular dependence of shading. We define the shading efficiency factor (Γ) as a percentage corresponding to the average shading ratio (μ) minus the standard deviation of this shading ratio (σ) for all viewing angles to be considered in the closed configuration, i.e. for $\theta < 60°$ and $|\varphi| < 60°$ (see above). Assuming a Gaussian distribution of these angular shading ratios, subtracting σ implies that the probability to have angular shading ratios lower than a specified Γ is of about 15%.

Based on these considerations and definitions, we establish, somewhat arbitrarily, the following two specifications with which our SVM must comply to best meet our high-level requirements #2 and #3:

A. In its open configuration, the shading ratio must be lower than 50%.
B. In its closed configuration, for $\theta < 60°$ and $|\varphi| < 60°$, one must have: $\Gamma > 90\%$

Direct into diffuse light transformation function (DDT). The DDT function efficiency (η) of the SVM is the ratio of direct sunlight transformed into diffuse light to the incoming direct sunlight in the closed configuration. Our specification for η is based on a benchmark and can be expressed as follows:

C. The DDT function of the SVM must provide daylighting at least equivalent to that provided by diffuse sunlight without a shading system (benchmark), throughout a whole typical meteorological year across the entire specific space considered.

Mechanical requirements. To reduce complexity and cost, no more than three shields must be used. To allow a simple and robust movement between the open and close configurations, as well as mechanical compliance with our passive actuation system, the mashrabiya shields S2 and S3 must move laterally (x-dimension) and vertically (y-dimension), respectively. Diagonal motions are not allowed.

Design and results

The final design of our SVM is the result of a trade-off between the mechanical and optical (A,B,C) specifications established above, while aiming for a mashrabiya-inspired design. Compliance with our mechanical specifications (three shields and orthogonal motions) is not easy to obtain given the conflicting specifications on shading for the open and the close configurations (max. shading ratio *versus* max. shading efficiency factor), in particular with the requirement of having a distance between the shield (Δz) and a mashrabiya-inspired design. Moreover, the shading efficiency factor (Γ), which must be maximized to meet the requirement for the closed configuration, decreases with the inter-shield distance Δz, while the DDT function efficiency increases with Δz, as explained later. What further complicates the design is that Γ does not vary as a function of Δz in a predictable manner because of the relatively complex geometry of the mashrabiya-inspired shield.

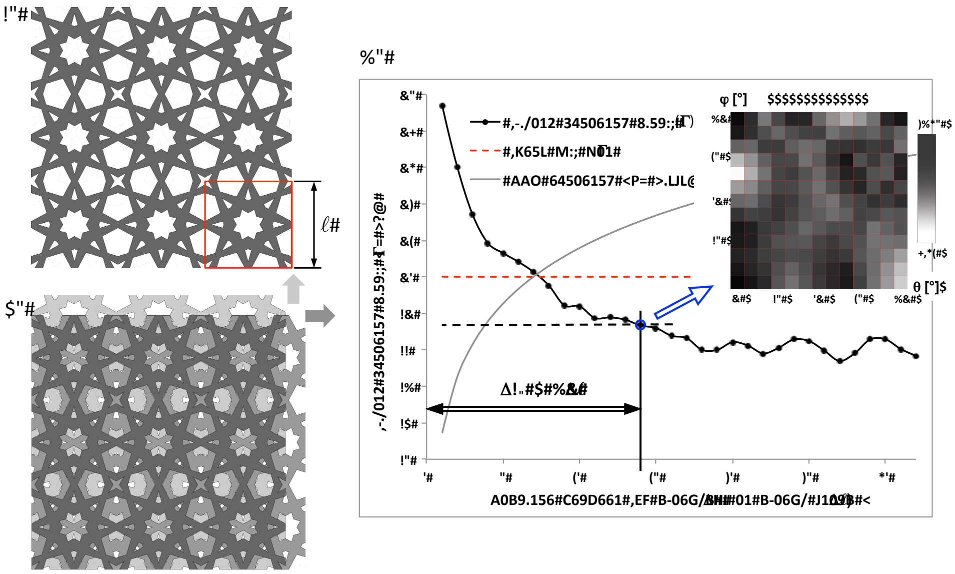

Figure 3 Resulting SVM design in (a) open configuration, and (b) closed configuration. (c) Plot of shading efficiency factor (Γ) and DDT function efficiency (η) against Δz, expressed in shield units $\Delta\ell = \ell/64$. Onset: Angular distribution of shading ratio at design trade-off distance $\Delta z_d = 14\Delta\ell$.

For our design, we used an iterative procedure with sequential calculations of Γ as a function of

Δz for different shield geometries till we found a viable trade-off. To get fast calculations of $\Gamma(\Delta z)$, we created a code in Grasshopper that calculates the shading ratio for all combinations of θ and φ angles varying in steps of 5° within the angular range ($\theta < 60°$ and $\varphi < 60°$), i.e., 169 combinations. The best trade-off we obtained led to the shield geometry shown in **figure 3 (a)**. The corresponding closed configuration is shown in **figure 3 (b)**. With this trade-off, we obtained a shading ratio of 54.1% and a shading efficiency factor of 88.7%, both values out of specifications (<50% and >90%, respectively). **Figure 3 (c)** shows the room for trade-off in the closed configuration between the variables Γ and η with conflicting trends.

Figure 3 (c) shows the plot of the DDT function efficiency $\eta(\Delta z)$, which corresponds to a fit across values calculated further in this paper. As shown in this figure, η increases with Δz with a horizontal asymptotic behavior while Γ, calculated with our Grasshopper code, decreases with Δz in a similar way. The distance Δz is expressed in a dimensionless unit corresponding to a fraction of the shield length motif (ℓ), which is $\Delta\ell = \ell/64$ (arbitrary choice). We used this unit because Δz ultimately only depends on the motif length, which is *a priori* unknown and remains a free design parameter (see below). In principle, to meet our specs for Γ, Δz must be smaller than $8\Delta\ell$ (**figure 3(c)**). For our trade-off, we preferred to have higher η at the expense of an only marginally lower Γ (88.7%) corresponding to $\Delta z_d = 14\Delta\ell$, which is the inter-shield distance used in our design. The **onset of figure 3 (c)** provides quantitative insights into the shading ratio versus the angle of view (θ and φ) at Δz_d.

Our design procedure has provided the shape of the shield and the relative size of the SVM structure ($\Delta z_d/\ell$). The absolute size of the SVM, i.e. $\Delta\ell$, and in turn Δz_d, was determined by a subjective appreciation of the most suitable scale of our SVM for best acceptability in its open configuration, with respect to interference with view to the outside and visual aspect in a room. To this aim, we carried out a brief survey based on a real-scale mock-up and computer rendering simulations. This resulted in a general consensus that a suitable motif size (ℓ) is of the order of ℓ = 16 cm. This value yields an amplitude of displacement $\Delta x = \Delta y = \ell/2$ = 8 cm and a distance $\Delta z_d = 14\ \Delta\ell = 14\ \ell/64$ = 3.5 cm.

DAYLIGHTING PERFORMANCE

To gain quantitative insights into indoor daylighting with our SVM, we need to evaluate the annual daylighting performance in a relevant case-study. Another specific goal is to determine whether our SVM - in its closed configuration - allows comparable or superior illumination than that provided by diffuse sunlight. First, we need to optimize the DDT function of our SVM.

Optimization of DDT function

The DDT function efficiency (η) of the SVM, i.e., the ratio of direct sunlight transformed into diffuse light to the incoming direct sunlight, mainly depends on three parameters: the angular intensity scattering distribution of the shield material - characterized by the "specularity" parameter (S) in RADIANCE, the distance between the shields (Δz), and the reflectance of the shield material (R).

To investigate the first two parameters (S and Δz), we opted for a brief sensitivity analysis by means of "point-in-time" simulations with the software DIVA-for-Rhino, which exploits RADIANCE algorithms. Light scattered by the SVM was measured as a function of S and Δz at a location free from any direct sunlight contribution (ceiling). First, the parameter S was varied in five equal steps of 0.2 between a Lambertian and a much more specular intensity scattering distribution (S = 0.1 and S = 0.9 in RADIANCE, respectively). Quite surprisingly, the simulations revealed that η is nearly independent of specularity. The parameter Δz was then increased in five even steps between $\Delta z = \ell/10$ to $\Delta z = \ell/2$ = 8 cm. The simulation results revealed that η increases with Δz with a horizontal asymptotic trend. As shown earlier, this is the specification on Γ that sets a limit on η leading to the optimal trade-off distance of Δz_d = 3.5 cm. Due to lack of space, we do not provide all the details of this sensitivity analysis.

Given that η obviously increases with reflectance, such an analysis is not required for this parameter. However, since the maximum reflectance value is practically limited by the availability of suitable materials and by ageing - especially when exposed to outdoor conditions - it is essential to determine the minimum value for R that allows for compliance with our specifications on η (see above). One option to find the minimal R would be to carry out a sensitivity analysis by means of annual daylighting simulations. However, since these simulations are very time consuming (around eight days) with the available computer resources, and are thus impractical for such a sensitivity analysis, we opted for getting a rough estimate of the minimum R required using the method described below.

Determination of minimum reflectance: method and results. Our goal is to find out what is the minimal reflectance of our SVM that provides, in closed configuration, an illumination just superior to that provided by diffuse sunlight without any solar protection. Since our SVM is meant to be used in arid climates, we chose to carry out our investigation for Abu Dhabi (latitude 24.47°). Our method relies on point-in-time simulations with average values representative of the typical climate that prevails at this location. Calculation of the average diffuse sunlight - which corresponds to our benchmark - is based on the yearly average of all data for diffuse horizontal irradiance (between sunrise and sunset) provided in typical meteorological year (TMY) files. For Abu Dhabi this value was found to be equal to 130 W/m^2. In a similar fashion, calculation of direct average sunlight illumination was based on the yearly average of all TMY data for direct horizontal irradiance with elevation and azimuth angles falling in the angular range corresponding to the closed SVM (same range as used for the calculation of Γ). We found a value of 479 W/m^2, which is used in our simulations at the mean angle of the range considered, i.e., at an elevation angle of 30°. Our calculations, which are performed with the Perez sky model in DIVA-for-Rhino, account for both the direct and the diffuse sunlight contributions.

Our simulation model consists of a rectangular volume with a square side covered by our SVM. We use one millimeter thick shields made of ten by ten motifs, corresponding to a size of 160 by 160 cm². To avoid direct sunlight, we calculated the illuminance as a function of the distance for the SVM (I(z)) along an axis centered on the ceiling-wall of our space, which is delimited by fully absorbing walls. The material of the shields had Lambertian scattering properties (S = 0, in RADIANCE).

Results and analysis. The results of our sensitivity analysis for the reflectance, obtained with point-in-time simulations using the method described above, are shown in **figure 4 (a)**. The illuminance I(z) calculated on the ceiling measurement axis is plotted for a few reflectance values (R=0.5, R=0.7, R=0.8, R=0.9) against our benchmark corresponding to yearly average diffuse sunlight in Abu Dhabi. These plots correspond to exponential fits through average illuminance values calculated at forty evenly spaced sensors along the ceiling measurement axis, which is approximately 210 cm long.

These results suggest that a reflectance larger than R = 0.7 gives an indoor illuminance slightly larger than that obtained with average diffuse sunlight conditions. Compliance with this key specification for R is demanding but still practically attainable with widespread materials.

Our relatively simple method can only provide rough figures for the benchmark and reflectance plots. Indeed, our point-in-time simulations are based on average quantities for diffuse and direct sunlight, and on a single average incidence angle for the latter. Moreover, we need to account for both spatial and temporal distribution of illuminance on the whole measurement plane. Annual daylighting simulations can provide more comprehensive and reliable figures, and improve our estimate of R.

Annual daylighting performance

Method. For the annual daylighting simulations, we considered a standard room with a West-facing glass wall. We analyzed and compared the annual daylighting performance obtained for three cases: a double pane glass wall without shading system, standard Venetian blinds and our SVM. The Venetian blinds are mounted on a double pane glass wall with 65% transmission, whereas the SVM in mounted on a double pane glass with low-E coating yielding 80% transmission. The room has a depth, width and height of 5 m, 3.52 m and 3.04 m, respectively. The sensor plane lies at a height of 85 cm with a clearance of 60 cm from the walls. This yields a sensor plane of 2.32 m x 3.8 m, which was divided into a grid of 160 sensors, each measuring 23.2 x 23.75 cm. The floor, walls, and ceiling were modeled as Lambertian scattering surfaces with a reflectance of 0.3, 0.65 and 0.8, respectively. The SVM shields have a reflectance R = 0.8 and Lambertian scattering properties. The configuration of the SVM, as well as the orientation of the Venetian blinds, are determined by the angle of incidence of direct sunlight according to the acceptance angle specified for our solar responsive actuation system (see above).

For our calculations with the Venetian blinds, we used the same simplified model as implemented in the DAYSIM interface, in which three tilt angles (β) of the blinds are determined by the solar incidence angle (θ) depending on specific angular thresholds. We used $\beta = 0°$ for $\theta < 15°$, $\beta = 30°$ for $15° < \theta < 30°$, and $\beta = 60°$ for $30° < \theta < 90°$, where β is taken relative to the window surface. This model uses standardized occupants behaviors. In the so-called "passive" behavior used here, the occupant leaves the blinds in their horizontal position ($\beta = 90°$) for long times dominated by diffuse sunlight (e.g. in the morning for a West-oriented façade). An algorithm, which we wrote in Python, was used to determine the moments throughout a typical year (8760 hours) corresponding to the specific angles that determine the sequence of actuation for either shading systems considered (SVM and blinds). The illuminances corresponding to this sequence, which are calculated by DIVA-for-Rhino with the Perez sky model, are used for the calculation of temporal maps.

Results and analysis. Temporal maps are used to present the results of our annual daylighting performance simulations obtained for a double pane glass wall without shading system, with standard Venetian blinds, and with our SVM made of shields with reflectance R = 0.8 (**Figure 4 (b)**). The triangular color scale allows showing the Acceptable Illuminance Extent (AIE), introduced by [Kleindeinst *et* al. 2012] to provide a visual representation of the fraction of our sensor grid that is above, below or within the illuminance range considered. Our range, which we call useful daylight illuminance autonomous (UDI-a), following Marjalevic's definition, is defined by bottom and top boundaries of 500 and 3000 lux (sharp cut-offs), respectively [Mardjalevic, 2009].

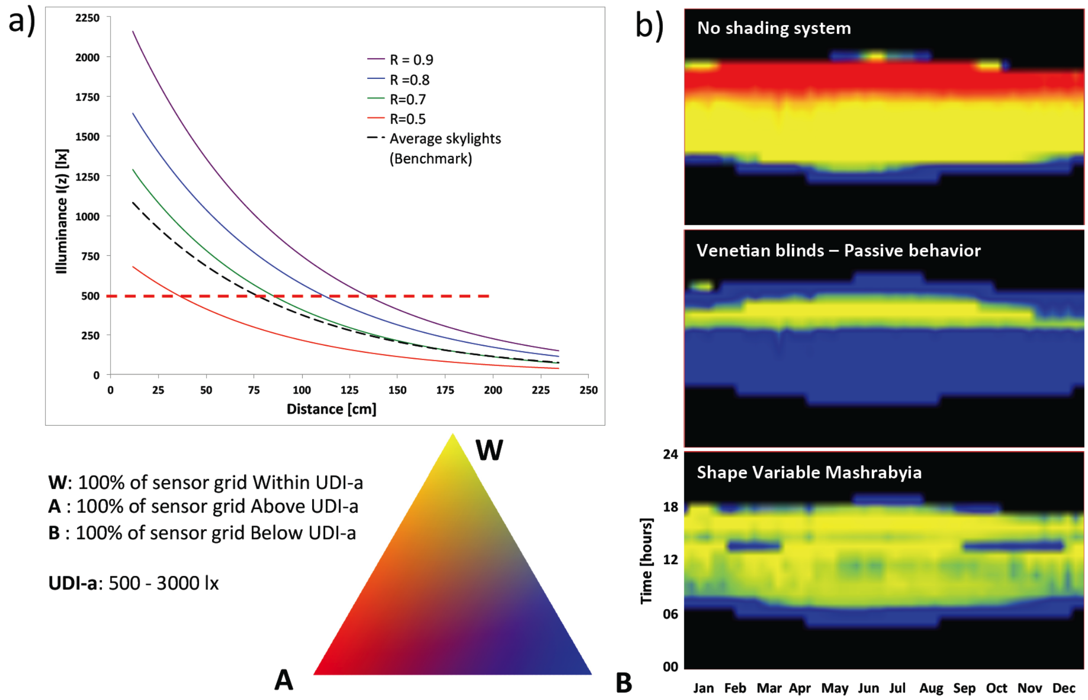

Figure 4 Annual daylighting performance for a West-facing room. (a) Average-based point-in-time simulations for closed SVM. (b) Temporal maps for three cases, including closed SVM with shield reflectance R = 0.8. Triangular color scale allows showing spatial intensity distributions.

Without a shading system, illuminance exceeds our high boundary of 3000 lux nearly all afternoon-times (solar noon to sunset) for most of space, as expected for a West-orientation. During morning-times (sunrise to solar noon), illuminance falls within the UDI-a boundaries (500 – 3000 lx) for the whole space except at dawn-times. With Venetian blinds, assuming passive occupants behavior, illuminance falls within the UDI-a boundaries only in the middle of afternoon-times and below the low-

UDI-a boundary of 500 lux for the rest of time. At sunset-times, when Venetian blinds must block abundant direct sunlight, which quite absurdly yields insufficient daylighting, the DDT function of our SVM manages to ensure adequate daylighting. This key design-objective for our SVM was translated into a specification for the DDT function efficiency that we are now in a position to assess in more detail than with our simple investigation based on average point-in-time simulations. Comparing the illumination obtained with our closed SVM exposed to direct sunlight (afternoon-times) *versus* illumination produced by diffuse sunlight only, i.e. without shading system during morning-times, reveals that adequate illumination is reached in both cases. However, when considering the whole temporal map with spatial information, illumination with diffuse sunlight proves to be slightly superior than with our closed SVM made of shields with reflectance of 0.8 under direct sunlight. In principle, this reveals that the efficiency of our DDT function (η) is slightly below our specification and that the above mentioned simple investigation was too optimistic.

However, a thorough investigation (outside of the scope of this paper) revealed that our simulation provides reliable trends for spatial illuminance distributions but underestimates the amount of diffuse light scattered by the SVM, i.e. η. Such a bias is caused by an insufficient number of simulation iterations imposed by the lack of available computational power. This investigation was based on the comparison of point-in-time simulations with corresponding measurements on a mock-up of our SVM. Further investigation is needed to estimate more accurately the magnitude of this bias and reliably account for it in our results. This mock-up was also used to get insights into aesthetics of our SVM.

DISCUSSION AND CONCLUSION

We have presented the design of a shading and daylighting system customized for arid climates focused on also preserving a Middle Eastern architectural character. Such a kinetic system design, which we named "shape variable mashrabiya" (SVM), strives to maximize visual comfort and minimize solar gains, while potentially coping with the harsh local environmental conditions. Our SVM enables to switch between an open and a closed configuration depending on direct solar irradiation. The latter configuration, which consists of a three-dimensional structure, blocks most incident sunlight while transforming a fraction of it into diffuse light used for indoor daylighting (DDT function).

Our results of annual daylighting performance simulations show that, thanks to its DDT function, our SVM provides adequate (within the UDI-a boundaries) and well-balanced (most of the time across the whole space) illumination, even in the presence of direct sunlight. In particular, in contrast to typical Venetian blinds, it provides sufficient daylighting under direct sunlight at low elevation angles. Considering that our simulations provide pessimistic figures for the DDT function efficiency (see discussion in last section), our results reveal that our closed SVM with shield reflectance of the order of 0.8 should provide comparable illumination than that obtained with diffuse sunlight. In addition to increasing daylight autonomy, i.e., allowing for energy savings, we believe that our SVM design bears some architectural value and aesthetic appeal that may favor its acceptability.

Future or ongoing work covers, among other things, the design and integration of the solar responsive system, the integration of an array of SVM into a facade, investigation of energy performance and field-tests to validate the robustness of our design in arid climates.

ABSTRACT

Based on the case study of two specific climatic contexts in the Andean tropic, this article sets out to demonstrate how the development of bioclimatic strategies can support architecture design in a variety of tropical climates, all this through the use of a bioclimatic profile applied to architecture.

INTRODUCTION

From nature's harmonious balance to the deterioration of the natural environment is a common path mankind has marked out through history. It's been this path on which architecture since the mid-twentieth century has left an aggregate ecological footprint with dire consequences for environmental balance and quality of life. The pursuit of human comfort in architectural design spaces at any price has been the main subject of debate among architects. The style and spectacle of architecture design has amply overridden (outstanding considerations regarding) the long-term sustainability of natural environments (López Morales, 2008).

It is from the foregoing background that the need for a more environment *responsive architecture* is drawn; the kind that can ensure quality of life going forward; one that allows for being permeated by climatic and geographic phenomena at all levels (Serra & Coch 2008); that is, one conceived from environment sustainability criteria to create conditions that promote healthful surroundings in comfortable living spaces (Givoni 1997; Serra 2009). In light of the above, it is safe to infer that moving away from an exclusively anthropocentric approach toward an ecological one represent an important challenge for modern-day architecture design.

The lack of Colombian research into the systematic design of bioclimatic strategies is the fundamental motivation for the study of a methodology of development of *bioclimatic profiles for architecture design*, which is the subject matter of this article.

AIM AND OBJECTIVE

Building a methodological reference, an ARCHITECTURE BIOCLIMATIC PROFILE, for climate analysis and a definition of bioclimatic strategies (for the Andean tropic), to be applied in two different Colombian climatic contexts.

CONCEPTUAL AND METHODOLOGICAL GUIDELINES

The work of this project takes an ecological approach to the design of passive strategies for building living spaces, which are conditioned by its surrounding variable environmental parameters and diversity of geographic phenomena. This as opposed to the design and construction of static environments in closed, airtight and rigid spaces, where sunlight and natural ventilation are replaced by mechanisms of artificial lighting and air conditioning (Serra, 2009 speaked about).

Colombia: Geographic and Environmental Context

Colombia lies in the Torrid Zone, which is characterized by high temperatures. Geographical factors and environmental parameters of the territory neutralize radiation received, making it possible for a variety of climates and ecosystems to coexist in a place, which would otherwise be remarkably hot, with a very high rate of radiation levels throughout its territory.

An abundance of geographic features, such as the Andes Range (Figure 1), mountains, lakes, swamps and rivers, sculpt the Colombian territory / topography. These make it possible for Colombia to enjoy a great variety of climates, which in turn make for the option of zoning the country strata and weather conditions, a decisive factor in achieving a better use of the solar energy resource in the construction of living spaces. This variety of conditions calls for very accurate information on the geographic and environmental determinants of each place, for the purpose of its bioclimatic characterization.

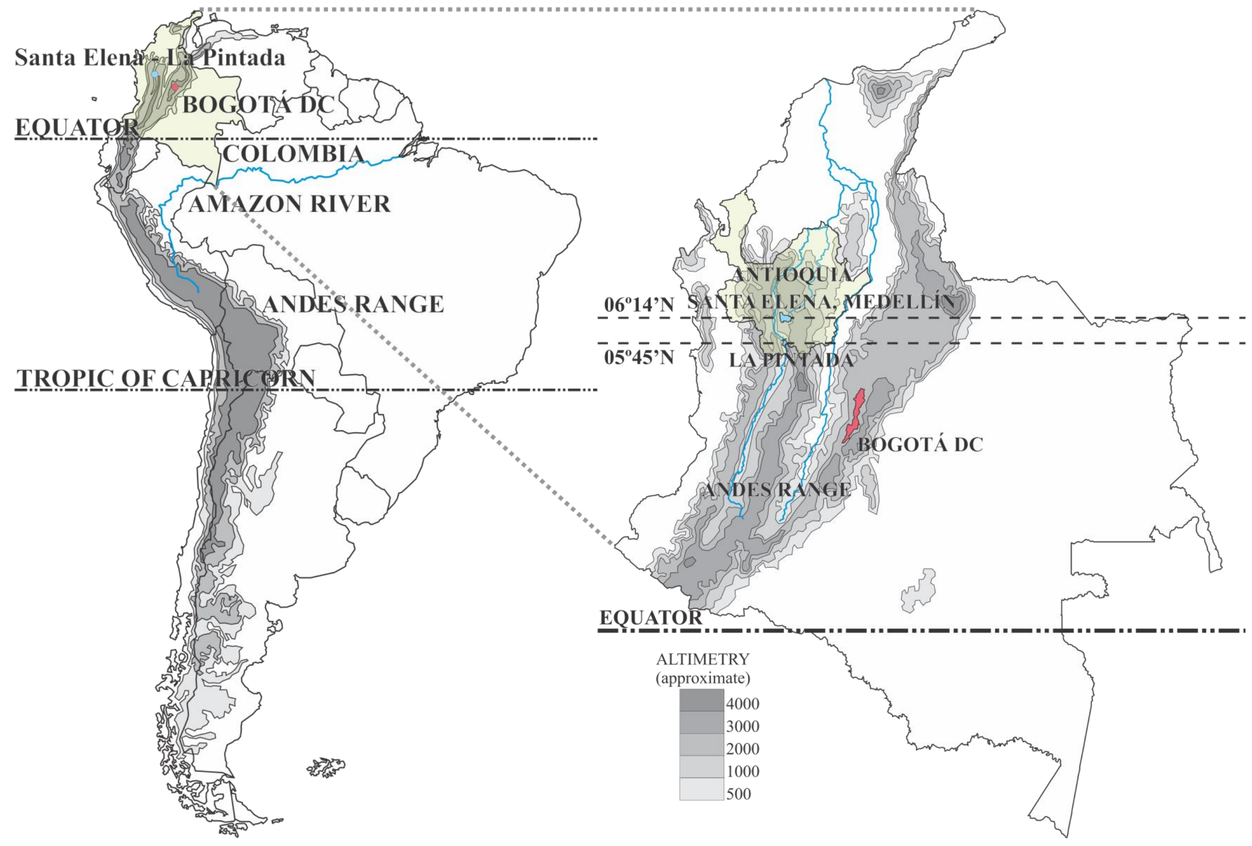

Figure 1 (a) Andes in Southamerica and (b) the Andes in Colombia.

Geographical factors related to latitude, altitude and orientation are required information, as they closely relate to the design of bioclimatic profiles in each context of the Andean region. Latitude, for instance, affects the angle of sunlight fall in both the dry and wet seasons, determining the risk of heat exhaustion and heat stroke. Altitude, on the other hand, affects the range of variability of air temperature throughout the year, which has an impact on ecological conditions (see Figure 2). The country's topographic orientation helps define the angle of incidence of sunlight, as well as the degree of exposure to the prevailing winds, which together account for the specific characteristics of ecosystems.

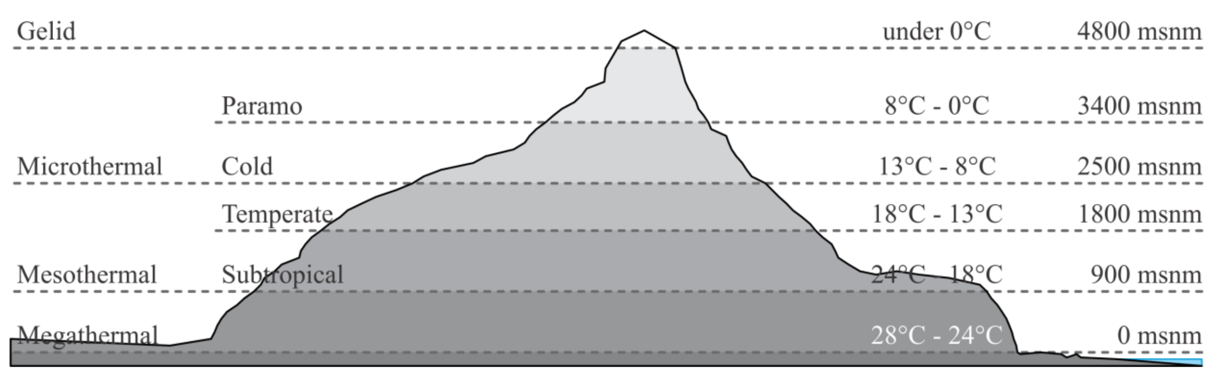

Figure 2 Schematic of geological strata by temperature.

Equally important are the environmental parameters that account for energy efficiency, which give rise to climate characterization of a territory and call for an adequate level of comfort and a decrease in pollution levels, allowing for a better experience of housing, appropriate to the climatic conditions that make up their environment.

This context presents us with the current problems faced by environmental design in architecture, especially how to resolve situations from the first developmental stages of a project, considering the efficient use of energy for a given set of geographical and environmental parameters of a project's location. The challenge is to build homes as close to the comfort zone as possible, regardless of location, whether located in climate areas as extreme as the high moors (see Figure 2), where temperature and radiation levels can be fairly low during periods of precipitation, or in the case of high temperature, low precipitation areas such as the ones found in deserts.

In terms of comfort, this work observes the rating scale proposed by McIntyre (1978) and further developed by Auliciems and Szokoloay (1997), which determines the range of temperature that can be considered comfortable for the user, known as the comfort zone, and by which it can be stated that the human body should make no metabolic effort to adapt to the environmental conditions of its surroundings, in order to feel well.

Considering the regulation of the indoor climate of buildings, has led to two different methodological approaches to addressing architectural design. One favors active strategies for climate control of buildings, with standardized criteria in design. The other favors passive strategies and considers the user as an active subject in the building, one who interacts with the environment through his relationship with architecture elements. Consequently, the definition of comfort zone is different for each bioclimatic profile, given that environmental conditions and variables are the subject of study that make up the profile.

In considering the regulation of indoor climate conditions, whether in a warm or cold tropical context, it is final orientation, which maximizes the solar resource as a source of heat and light energy, as well as, the need for ventilation. In short, the proper orientation, which is determined by the thermal bioclimatic profile, depends on which floor the project is located.

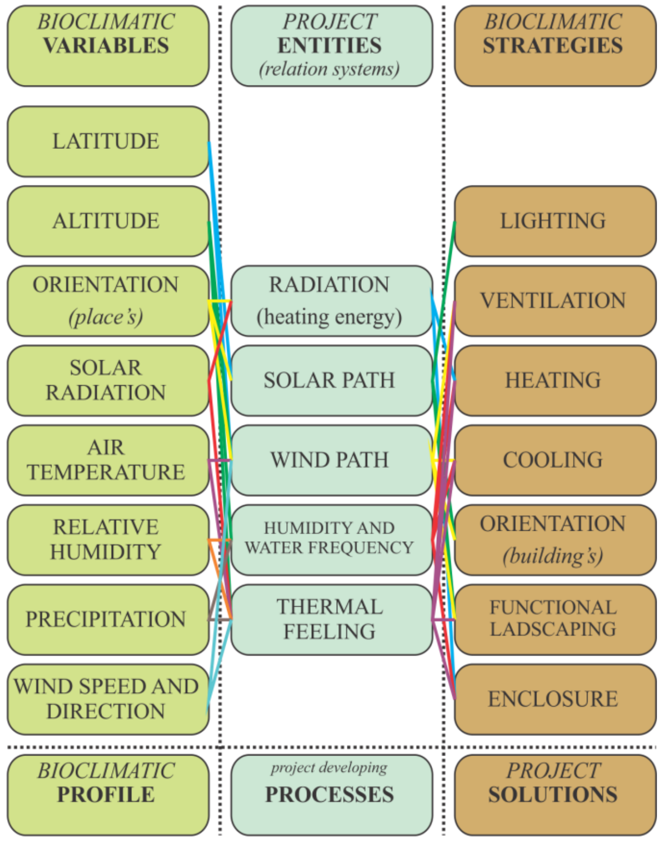

Figure 3 Methodological schematic.

Architecture Bioclimatic Profile

The purpose of an ***architecture bioclimatic profile*** is to identify the environmental variables that determine climate context, in order to analyze them in consideration of bioclimatic criteria necessary for making decisions at each stage of the architecture design process.

A project's architecture bioclimatic profile begins with the identification of those variables considered relevant, by virtue of their being constitutive of the climatic context, which affects directly the comfort of the project itself, namely, latitude, altitude, orientation, radiation level, (sunlight exposure), air temperature, relative humidity, precipitation, wind direction and speed. (see Figure 3). Climate data found through different national and international organizations are used to configure the climatic characterization of a place.

Data gathered on each of the above variables (see fig. 3, left column) become meaningful for an architecture project, once contextualized for its location, and analyzed from categories (see fig. 3, mid column) that take valuable information out of the data.

The information obtained from the characteristics of each variable reveals the energy potential available for the development of a particular architectural project. This constitutes the basis for determining the type of strategies to be implemented for energy efficiency and comfort, such as lighting, ventilation, heating, cooling, orientation, functional landscaping, and weatherization (see Figure 3).

As can be inferred from the above approach, the methodological structure of an architecture bioclimatic profile consists of a system of relationships that moves from raw data to meaningful information regarding the available energy resource, and from this, to the strategy. This proposal is a starting point to further developments concerning its subject matter.

APPLICATION OF ARCHITECTURE BIOCLIMATIC PROFILES TO DESIGN

Two towns located in northwestern Colombia serve as hosts and provide the context to implement the proposed architecture bioclimatic profile: The township of Santa Elena and the City of La Pintada, two territorial units attached to the Department of Antioquia, whose capital is Medellín.

Comparative Analysis of two Climatic Contexts

Prepared bioclimatic profile of each of the contexts to be developed (see Figure 4) A considerable climatic difference can be appreciated. It is attributable to the difference in altitude between one territory and the other (2000 m in total). Santa Elena is located atop a mountain ridge that divides two valleys, the Aburrá Valley, to the northwest, and the San Nicolás Valley, to the southwest, whereas La Pintada is nestled in the lower part of a valley which is crossed by one of the largest rivers of Colombia, and a section of whose is contoured by formidable canyons. The above characteristics are influential when analyzing the climate of an area in the Torrid Zone.

As a result of the differences identified in the bioclimatic profiles, the recommendations for bioclimatic strategies, that is the project design solutions, propose architectural designs whose adaptations vary between climates and territories. For example, lighting in St. Helena can use both direct radiation and scattered radiation, depending on air temperature and the time of day. So on the one hand, the need for solar energy is met. On the other, people can enjoy a convenient sunbath at certain times of day, when there is a chill factor. In contrast, in La Pintada, direct lighting is not recommended for a number of reasons, as it entails uncomfortable temperature increases, which are unnecessary in this place, and adversely affect the comfort of users.

As for ventilation, in Santa Elena active user intervention is recommended to ventilate the interior of living spaces, whereas in La Pintada, it is recommended that the architecture design incorporate constant ventilation systems to prevent overheating of units, and contribute to user comfort.

On the other hand, if we consider building orientation, alignment is done with taking into account the solar arc and air temperature, regarding the need for either ventilation, heating or cooling in the building, according to the characteristics of its bioclimatic profile. In short, all of the above decisions are interrelated thanks to the analysis of the architecture bioclimatic profile.

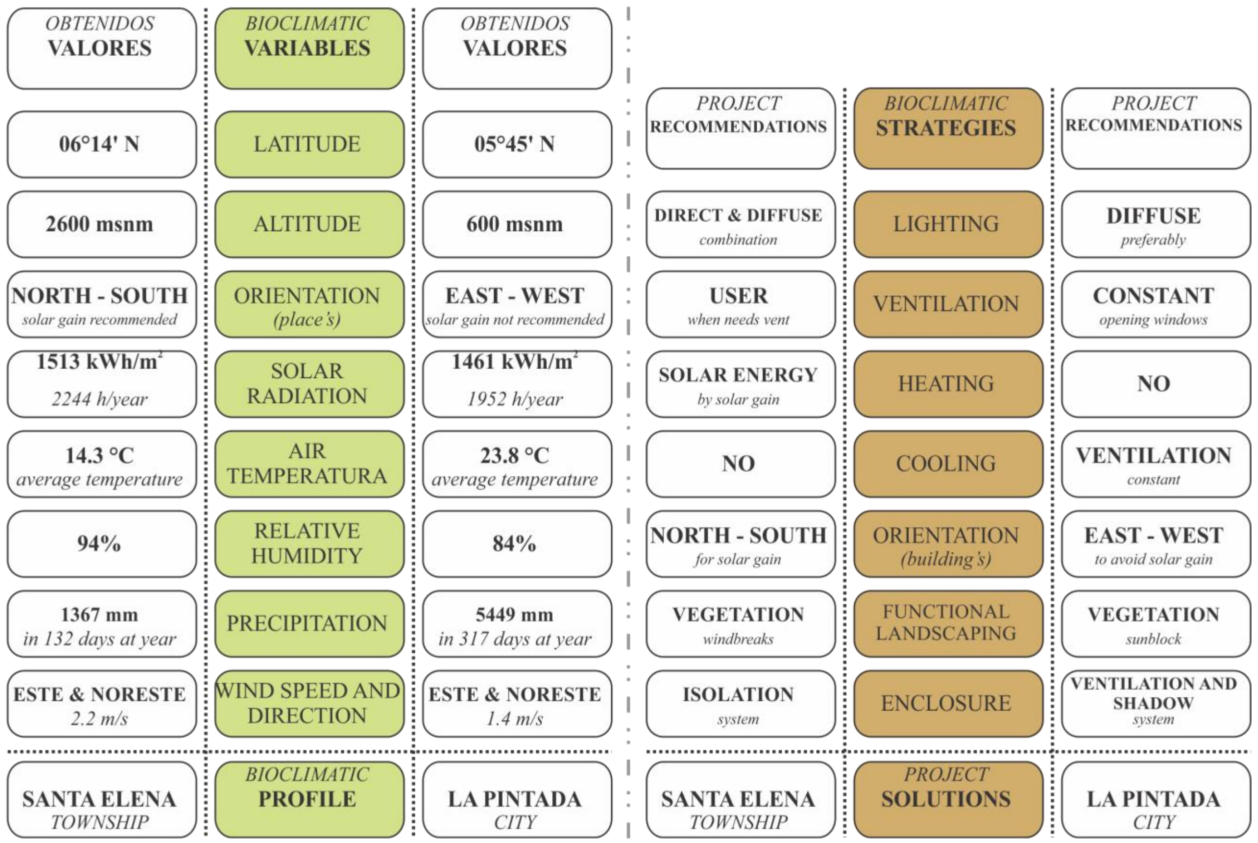

Figure 4 (a) Architecture bioclimatic profiles of Santa Elena and La Pintada; and (b) bioclimatic strategies of Santa Elena and La Pintada (climate values from IDEAM 2005; UPME & IDEAM 2005).

Based on the formula proposed by Auliciems and Szokoloay (1997), the temperature comfort zone for housing units in Santa Elena is lower than that in La Pintada (see Figure 5).

Santa Elena	La Pintada
$Tn = 17.6°C + (Tm * 0.31)$	$Tn = 17.6°C + (Tm * 0.31)$
$Tn = 17.6°C + (14.3°C * 0.31)$	$Tn = 17.6°C + (23.8°C * 0.31)$
$Tn = 22°C$	$Tn = 25°C$
Where	Where
$Zc = Tn \pm 2.5°C$	$Zc = Tn \pm 2.5°C$
Being	Being
$Tmin = 19.5°C$	$Tmin = 22.5°C$
$Tmax = 24.5°C$	$Tmax = 27.5°C$

MAKING INFERENCES AND DRAWING CONCLUSIONS

Making way for an ecological approach to architecture is akin to harmonizing the comfort of living spaces with the potential of its surrounding environment, to ensure the preservation of the planet and improve the quality of life of people.

The findings of this research lead us to summarize:

The architecture design of a project should start with the climatic characterization of the environment where it will be located. This approach stands in contrast to the principles of standard architecture design, in the case of different climatic contexts.

The architecture bioclimatic profile is the basis for building a system of relations between the bioclimatic characteristics of the environment, its energy potential and the strategies proposed for achieving comfort, (besides representing a methodological reference for the customization of each architecture project within its context).

In different climatic contexts, before implementing passive strategies, it's necessary to figure how to apply the available energy sources to the generation of human comfort.

Putting together an Achitecture Bioclimatic Profile for each project means creating responsiveness to expectations of users and conditions of the environment, consolidating the two into adequate living spaces, within the criteria of durability, comfort, and efficiency in the use of natural resources, and environmental sustainability.

The field of bioclimatic architecture should a more creative, interdisciplinary endeavor that is socially responsive. Therefore, the challenge lies in transitioning from a mindset predatory of the environment to one concerting of vital living spaces in harmony with its surroundings.

NOMENCLATURE

Tn = neutral temperature
Tm = average temperature
Zc = comfort zone
Tmin = minimum temperature of the comfort zone
Tmax = maximum temperature of the comfort zone
Gelid = is the climate level located from 4800 msnm, known as gelid because of its icy temperatures and corresponds to the perpetual snow height. Presents temperatures below 0°C.
Paramo = is the climate level located between 3400 and 4800 msnm presenting temperatures from 8°C and 0°C respectively.
msnm = meters above sea level

ABSTRACT

This paper reports on a research that utilized simulation techniques for identifying the most efficient hospital patient room designs and their associated window-to-wall ratios. Simulation of the energy consumption and daylighting performance of common patient room designs were conducted using a range of Window-to-Wall Ratios (WWRs). The paper focuses on arriving at solutions that balance between the reduction of energy consumption and the achievement of proper daylight distribution in the desert climate of Cairo, Egypt. Simulations were conducted using the Diva-for-Rhino, a plug-in for Rhinoceros modelling software to interface with the Energy Plus, Radiance and Daysim software. Results demonstrated that solar penetration is a critical concern affecting patient room design and window configuration in desert locations. Use of the outboard bathroom patient room design was found to be the least efficient among the tested alternatives. Although it has a smaller external wall size, it failed to provide energy consumption that is lower than that of the other options. Its best energy performance was 20% higher than that of the nested bathroom patient room design. However, the outboard bathroom design allowed for larger WWRs (70%-90%), which might prove useful for external view exposure purposes. The nested and inboard bathroom patient room designs provided better energy performance. However, this was on the expense of window size. The acceptable cases of these designs had smaller WWRs, (30%-40%). The results of this paper demonstrated the need for the careful consideration of the size of windows and openings in relation to different patient room designs. Simulation techniques can prove useful in this regard.

INTRODUCTION

Hospitals are typically considered one the most energy demanding building types. Patient rooms compose the largest volume of hospital buildings. The external walls of patient rooms represent the most significant part of the external surface area of these buildings. Windows can contribute significantly to the healing process and reduction of pain and length of stay in hospitals through the provision of daylight and allowance of external view (FGI, 2010). However, they can also contribute negatively to the energy consumption of these buildings, especially in desert climates, where the cooling load represents a significant percentage of total energy consumption.

Sizing the windows of patient rooms should be carefully considered in relation to patient room shape. Some common patient room designs have a small external wall surface area with a large room depth, while others have larger external room surfaces and a reduced depth of the work area. The windows of patient rooms should minimize solar penetration, reduce overheating; yet at the same time maximize daylighting and patient access to external view. The objective is to reduce the total energy load while maintaining comfort and quality health care.

Literature addressed the effect of environmental aspects on healthcare delivery. Ulrich recommended that natural light improvement could help reduce stress and fatigue, while increasing effectiveness in delivering care, patient safety and overall healthcare quality (Ulrich, 1991 and Ulrich et al., 2004). In an attempt to develop patient room designs to create healing environments, the effect of natural daylight on the patients' average length of stay in hospitals was investigated. Studied factors were patient's average length of stay as an index of health outcome, and the differences in environment during daylight hours, such as illuminance, luminance ratio, and illuminance variation in the hospitals patient rooms (Choi et al., 2012).

In research work more relate to this study, energy efficient building envelope treatments were examined for a generic reference hospital in Thailand. Parametric analysis was conducted. The overall thermal transfer value, glazing material, Window-to-Wall ratio (WWR) and external shading devices were addressed. The annual energy savings due to increasing daylighting reached up to 15.4% and 11.3% for the electrochromic and green tinted glazing respectively (Chungloo et al., 2001).

Optimization of window opening in a hospital patient room was addressed in a research that aimed at providing daylighting, external view, while minimizing the energy consumption. An optimization methodology was demonstrated through parametric computer simulations to determine the optimum window design in the form of window width, sill and lintel heights and shading device depth (Shikder et al., 2010). The impact of using various window shading systems and different window glazing types on the energy consumption of a typical hospital Intensive Care Unit room space in Egypt was examined. It was found that energy savings reaching up to 30% could be achieved by the use of externally perforated solar screens and overhangs positioned at a shading angle of 45° (Sherif et al., 2013-a).

In another study, daylighting performance was simulated for a typical hospital Intensive Care Unit room space located in Cairo, Egypt. Several window configurations were simulated in the four main orientations, where the effect of adding shading and daylighting systems was examined. Successful window configurations were recommended for different window to wall ratios (Sherif et al., 2013-b).

The above review of literature demonstrates that a limited number of publications addressed with the relationship between hospital patient room designs and the associated window configurations. Research work concerned with this relationship in desert environments is almost nonexistent. Configuring the windows of patient rooms for energy efficiency, while providing acceptable daylighting levels, could pave the way for reaching more sustainable hospital designs.

OBJECTIVE

This paper aimed to compare the energy consumption and daylighting performance of common hospital patient room designs. Investigation focused on the design of windows facing the south orientation under the desert clear-sky of Cairo, Egypt. The larger aim was to arrive at satisfactory patient room designs that minimize energy consumption and maximize the utilization of daylighting, thus help improve the delivery of sustainable healthcare facilities.

METHODOLOGY

The methodology was divided into two consecutive stages. Stage one investigated the energy performance of the tested patient room design cases along with the alternative window configurations. Stage two concentrated on the analysis of daylighting adequacy for the cases which achieved acceptable performance in stage one. Three of the most common patient room designs were selected for investigation. These were: Design A: the outboard bathroom patient room design; Design B: the nested bathroom patient room design; and Design C: the inboard bathroom patient room design. The tested rooms were assumed to have a similar floor area (22 m²). The layout, dimensions and parameters of the tested rooms are shown in Table 1 and Figure 1.

Table 1. Parameters of the Tested Patient Room.

Internal Surfaces Materials		
Walls	*Reflectance*	*50% (Medium Colored Internal-walls Off-White)*

The Inboard Bathroom

Figure 1 The tested patient room designs

Seventeen window size values, expressed as Window-to-Wall Ratios (WWRs) were analyzed for each patient room design. The values ranged from 10% to 90%, at 5% increments. The shape and location of the tested windows alongside the external wall of the patient room space are illustrated in Figure 2. A horizontal sun breaker was assumed to be positioned on top to the window. Its overhang value provided a sun protection angle of 45°, as shown in Figure 3. This angle was based on the results of previous research work (Sherif et al., 2013 b).

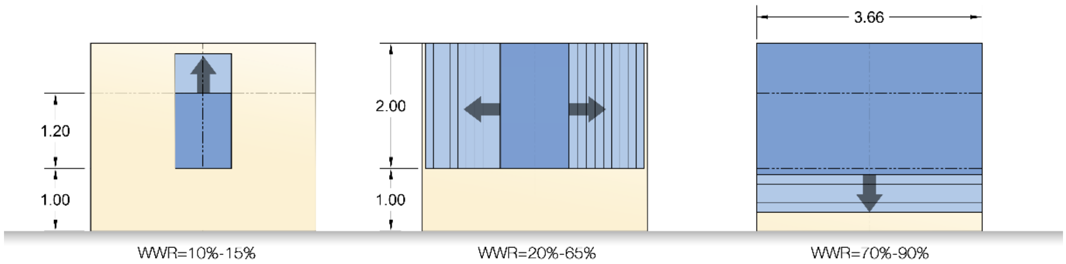

Figure 2 The shape and position of the tested window on the external wall at different WWRs.

Simulations were conducted using the climatic data of the city of Cairo, Egypt (30°6'N, 31°24'E, alt.75 m) that enjoys a year-round desert clear-sky. The city is characterized by a hot-arid desert climate, according to Köppen-Geiger (2006). The tested patient rooms were assumed to be located on the second floor level of a hospital building, where windows were assumed to face no external obstruction. The external ground surface was assumed to have a 20% reflectance value. Grasshopper which is a plugin for Rhinoceros modeling software and a parametric modeling tool was used to automate the energy and daylighting simulation process. By activating this function, the Grasshopper plugin generated a parametric model for each WWR and ran a climate based analysis through DIVA interface. Energy simulation was conducted using the EnergyPlus software. Daylight simulation was conducted using the Radiance and DAYSIM software. The Diva-for-Rhino plugin for the Rhinoceros modeling software was used as an interface.

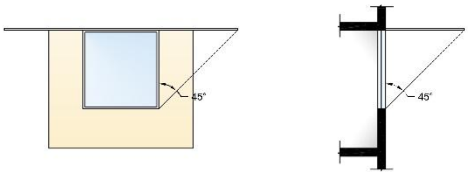

Figure 3 The overhang of the shading device protecting the tested window.

Methodology of Stage One: Energy Consumption Analysis

The aim of this phase was to investigate the energy consumptions associated with the three tested patient room designs (cases A, B and C). The annual energy consumption resulting from the different WWRs of each patient room design was calculated. The cooling, heating and lighting energy consumption values were accounted for. The WWRs which resulted low energy consumption values falling within 3% from the lowest value for a certain patient room design were considered acceptable cases for such as design.

Energy simulation parameters were selected to focus on studying the performance associated with room shape and window configuration. The effect of thermal transmittance through walls and ceiling from the adjacent spaces was neutralized. Thus, the thermal transmittance from all walls and ceiling, except that of the window wall, were set to be adiabatic. The effect of the adjacent rooms was considered to be of no relevance to the thermal performance sought in this comparative study. The building was assumed to be fully air conditioned and minimal thermal transmittance was expected from the other internal spaces that would have identical set conditions. The external wall was defined as a 0.35 m thick double brick insulated cavity wall with a U- value of 0.475 W/m² –k that carried the tested window at its center. The air conditioning system heating and cooling set points were assumed to be 22°C/26°C respectively. The occupancy time of the studied patient room was chosen to be all day, at a rate of 10 m²/ occupant. The hourly lighting schedules that were generated through the annual Daylight Availability analysis by the Radiance and DAYSIM software were used as basis for artificial lighting energy calculations. This artificial lighting was set to be dynamically controlled by sensors according to daylighting adequacy.

Methodology of Stage Two: Daylight Availability Analysis

The aim of this stage was to evaluate the year-round daylighting performance of the cases that proved successful for each of the three design configurations in stage one. Simulation parameters used in investigations were: ambient bounces = 6; ambient divisions = 1000. The occupied time of the patient room was assumed to be from 06:30 AM to 10:30 PM. In this study, the reference plane on which daylighting performance was simulated was the patient bed level plane (0.90 m height). The spacing of the analysis grid was set at 0.7m * 0.7m. Four points were placed on the patient bed. The reference plane contained 46, 54 and 53 measuring points in each of the three tested patient room designs A, B and C respectively, as shown in Figure 1. The illuminance value was assumed to be 300 Lx (IESNA, 2000).

Three Daylight Availability evaluation levels were used (Reinhart & Wienold, 2011). First, the "daylit" areas were those areas that received sufficient daylight at least half of the year-round occupied time. Second, the "partially daylit" areas were those areas that did not receive sufficient daylight at least half of the year-round occupied time. Third, the "over lit" areas were those areas that received an oversupply of daylight, where 10 times the target illuminance was reached for at least 5% of the year-round occupied time. Two daylighting acceptance criteria had to be satisfied. First, 100% of the patient bed surface area should be "daylit". Second, at least 50% of the patient room area should be "daylit".

SIMULATION RESULTS

Results of Stage One: Energy Performance

The total annual energy consumption values expressed in Kwh/m² were calculated. The results are as shown in Table 2. It summarizes the energy consumption results in the south orientation at different WWRs for the three investigated room designs A, B and C. The cases that achieved the required threshold were highlighted with a light tone in the table.

Table 2. Total Annual Energy Consumption for Layout Designs A, B and C

Annual Energy Consumption (Kwh/m2)																	
WWR%	10	15	20	25	30	35	40	45	50	55	60	65	70	75	80	85	90
Design A	180	192	189	186	184	182	177	178	177	177	176	176	173	175	174	175	176
Design B	169	168	153	151	147	147	147	150	154	158	162	167	171	174	177	180	183
Design C	173	175	166	158	154	151	155	158	160	161	163	169	174	177	178	180	183

Use of design B that has a nested bathroom resulted in the lowest energy consumption among all three room design types. The consumption was as low as 147Kwh/m2 in WWRs 30%-40%. Moreover, design C (inboard bathroom design) achieved a very close value of 151 Kwh/m2 in WWR 35%. Use of these designs resulted in a better performance in comparison with Design A (outboard bathroom design) which failed to produce a value lower than 177 Kwh/m2. Furthermore, use of Design A resulted in the highest energy consumption among all alternatives. It reached 192 Kwh/m2 at 15% WWR. On the other hand, its consumption was lower than the other two alternatives at high WWR values. Using a 90% WWR with designs A and B resulted in comparatively larger energy consumption values, reaching up to 183Kwh/m2.

On the other hand, the outboard bathroom design configuration (Design A) achieved larger window sizes and larger number of options in comparison with the other two layout configurations. The acceptable WWR range of Design A extended from 40 to 90%. Fewer acceptable WWR choices and smaller window sizes were identified for the nested bathroom configuration (Design B). These ranged from 20% to 45% WWR. A very limited range of WWRs was found acceptable in the inboard bathroom configuration (Design C), where only three WWR cases (30 to 40% WWR) met the required criterion. In design A, the bathroom location on the outboard wall reduced the size of the exposed external wall surface, thus reducing the thermal exposure of the patient's room to the hot desert climate. However, this was overcome by the increased artificial lighting energy load, as explained later. This was not the case in the nested and inboard designs, where the size of the external wall surface was much larger.

To explain the behavior described above, the lighting, cooling and heating consumption values were analyzed. As expected for a desert environment, cooling represented the highest values, followed by lighting electricity then heating loads, which were almost negligible as shown in Figures 4, 5 and 6.

The performance of design A is shown in Figure 4. The lighting electricity load significantly decreased with the increase of WWR. This could be attributed to the increase of daylighting use, which resulted in a reduction of artificial lighting. However, the nature of the patient room plan type resulted in overall higher levels of artificial lighting, with subsequent high cooling energy. On the other hand, the cooling energy loads slightly increased with the increase of WWR. This allowed the acceptance of larger WWRs, reaching up to 90%. The use of an outboard toilet with the resultant small external wall surface dampened the effect of changing the WWR. This was observed in the gentle curve slope of the cooling energy consumption for WWRs 20%-90% that it is almost flat.

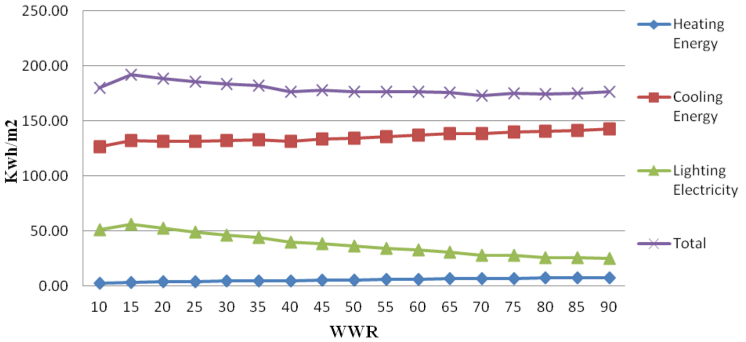

Figure 4 Design A annual cooling, heating, lighting and total energy loads for different WWRs.

The performance of Design B is shown in Figure 5.The lighting electricity load decreased at a constant rate with the increase of WWR, while the cooling energy loads increased considerably with the increase of window to wall ratio (WWR). This is observed in the considerable increase and the curve slope of the cooling and the total energy use from 40% to 90% WWR. This could be attributed to the design of this patient room type that has a nested toilet that is associated with a larger external wall surface. This increased solar exposure and allowed the window transmitted solar energy.

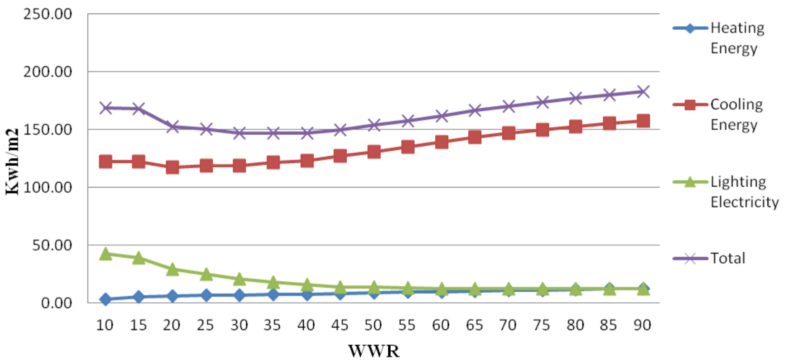

Figure 5 Design B annual cooling, heating, lighting and total energy loads for different WWRs.

The energy consumption of patient room Design C is shown in Figure 6. This design was found to produce behavior almost similar to that of Design B. Both share a large exposed external wall. It was noticed, thought that the cooling energy of design C was slightly higher than that of Design B. This could be attributed to the cooling load resulting from the slightly increased lighting electricity.

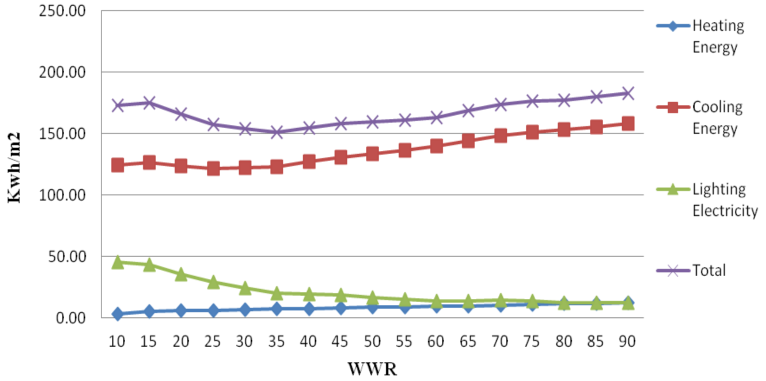

Figure 6 Design C annual cooling, heating, lighting and total energy loads for different WWRs.

Results of Stage Two: Daylight Availability Analysis

In this stage, the cases that achieved successful energy performance in stage one were evaluated for daylighting adequacy. Results are shown in Table 3. In Design A, acceptable daylight availability was only achieved at large WWRs. Only 5 of the tested cases passed the daylight availability test in this case. On the other hand in Design B, 4 of the 5 tested cases resulted in acceptable daylighting performance. In Design C, all of the three tested cases resulted in an acceptable daylighting performance.

Table 3. Percentage of "Daylit" Area Relative to Patient's Room and Bed Plane Areas

WWR %		25	30	35	40	45	50	55	60	65	70	75	80	85	90
Design A	Room				26	28	35	39	43	48	54	61	63	72	70
	Bed				0	25	100	100	100	100	100	100	100	100	100
Design B	Room	41	54	57	65	80									
	Bed	100	100	100	100	100									
Design C	Room		60	58	62										
	Bed		100	100	100										

For more detailed discussion, eleven cases were analyzed for the outboard bathroom design (Design A). Simulation results revealed that the amount of acceptable "daylit" areas was directly proportional to the increase of WWRs values. Only large windows achieved adequacy in the case of the outboard bathroom design. For WWRs between 70% and 90%, the "daylit" area reached 72% of the space area, especially at 85% WWR. The "partially daylit" areas dominated the patient room, where it reached 50% of the space in average (40% to 65%). However, it decreased gradually until it became unnoticeable at 85% WWR (15% of the space). In contrast, the "overlit" area was almost constant (13% as an average) in the tested WWRs.

On the other hand, when the bathroom was located in-between two adjacent patient rooms (Design B: The nested bathroom), only four cases from five energy efficient ones achieved adequacy (30% to 45% WWRs). The "Daylit" area reached 80% of the space, at a WWR value of 45%. Although, the "daylit" area of the patient bed plane achieved adequacy in the 25% WWR case, it was unacceptable in relation to the overall patient room area testing (41% "daylit" area). The "Partially daylit" area decreased gradually until it almost disappeared (1%), in the case of 40% WWR.

For the inboard bathroom design (Design C), the three energy efficient cases (30%, 35% and 40%WWRs) were acceptable for daylighting performance. The "daylit" area values for the patient room space were almost similar (60% at an average). For the three design configurations, the "over lit" area percentages did not exceed 15% in average for overall the patient room space in all accepted daylight availability cases.

CONCLUSION

The energy and daylighting performance of three common patient room designs were simulated. The performance resulting from use of a range of window sizes (expressed as Window-to-Wall Ratios - WWRs) under the clear-sky desert sun of Cairo, Egypt was examined for each of these room designs. Table 4 summarizes the range of WWRs that were recommended for each patient room design for satisfying the energy and daylighting criteria. In addition, the balanced WWRs that satisfy both energy and daylighting criteria at the same time were identified.

Results of this study demonstrated that solar penetration is a critical concern affecting patient room design and window configuration in desert locations, like in Cairo, Egypt. Use of the outboard patient room design was found to be the least efficient among alternatives. Although it has a smaller external wall size in comparison with the other alternatives, it failed to provide an energy consumption that was lower than that of other two tested room designs. Its best energy performance was 20% higher than that of the nested bathroom design. This could be attributed to the increase of artificial lighting that resulted from allocating the bathroom along the external façade in the outboard bathroom design. However, the outboard design allowed for larger WWR values. This might prove useful for external view exposure purposes. Although the nested bathroom and inboard bathroom designs provided better energy performance, this was on the expense of window size. The acceptable cases of these designs had smaller WWRs, between 30% and 40%.

The results of this paper demonstrated the need for a careful consideration of the size of windows and openings in relation to different patient room designs. Simulation Techniques proved useful in identifying the wiNdow configurations that satisfy both the energy and daylighting requirements at the same time.

ABSTRACT

The built form alters the microclimate significantly which in turn affects the outdoor thermal comfort. The outdoor thermal comfort depends on the ability of the materials to absorb solar radiation (albedo) and the geometrical arrangement of the buildings and its morphology. The aim of this study is to investigate the influence of the built geometry and its morphology on the outdoor thermal environment in an institutional campus in the hot humid city of Chennai. The study is twofold. Firstly, the impact of built geometry on the microclimatic conditions was assessed through field measurements and secondly a questionnaire survey on thermal sensation in the campus environs of Sathyabama University was conducted to study the subjective response of students to the outdoor thermal environment in a hot humid climate. The field measurements included the monitoring of meteorological parameters such as air temperature Ta, relative humidity RH, wind speed v and mean radiant temperature Tmrt. Outdoor thermal comfort conditions were assessed through the physiologically equivalent temperature (PET) index, during daytime at different built morphology. The influence of various built parameters such as Sky view factor (SVF), building materials, green cover, etc., on microclimatic conditions and the daytime thermal sensation were assessed. This study also attempts to identify various passive design options in order to arrive at favourable microclimatic conditions and to improve pedestrian comfort conditions during daytime in an institutional campus.

INTRODUCTION

The built form alters the microclimate significantly which in turn affects the outdoor thermal comfort. Built form is characterized by replacement of the natural earth's surface by hard impervious layer; buildings and its geometry; and the properties of the dense construction materials. Also, the outdoor thermal comfort depends on the ability of the materials to absorb solar radiation (albedo), the geometrical arrangement of the buildings and its morphology. The dense construction materials stores the heat and increases the surface temperature, the building geometry (defined by the ratio of height of the buildings to the width of the street) traps the incident solar radiation, the hard impervious pavements, roads and parking lots increases the surface runoff of water and the reduced vegetation increases the air temperatures at the microclimate level thus influencing the thermal comfort of the pedestrians. Enhancement of the outdoor thermal comfort is possible through careful analysis of the built form and its influence on the microclimatic parameters. Therefore, this paper aims at investigating the influence of the built geometry and its morphology on the outdoor thermal environment in an institutional campus in the hot humid city of Chennai.

Ebin Horrison is a research Scholar and Surya Rajumar is a Postgraduate student at the Department of Archiecture, Faculty of Building & Environment, Sathyabama Univeristy, Chennai, India.

BACKGROUND LITERATURE

At the micro level, building geometry shows an intimate relationship with air temperature, and Oke (1976) states that the thermal climate at the canopy layer depends on the characteristics of the individual site and not on the temperature at boundary layer. The height-to-width ratio and the street orientation with respect to solar radiation, was found to have a great influence on the timing and magnitude of the energy regime of the individual urban surfaces (Nunez and Oke 1977). Oke (1981) states that the rate of cooling at the street level depends on two parameters: the Height – width ratio (H/W, street geometry) – the ratio of typical height of the buildings to typical width of the neighbouring streets and the sky view factor - the fraction of the sky hemisphere visible from a location at the street level in an infinitely long urban street canyon. Arnfield (1990) compared the effects of urban geometry and thermal properties of the construction materials and found that the canyon geometry is the predominant factor and the thermal properties of the materials enhance the differences in the cooling rates generated by different street geometries. The canyon radiative geometry contributes to a decrease in the long-wave radiation loss from within the street canyon due to the complex exchange between buildings and the screening of the skyline and decreases the effective albedo of the system, because of the multiple reflection of short-wave radiation between the canyon surfaces (Oke et al 1991). Ahmed (1994) found a decrease in air temperatures by 4.5K with an increase in the H/W ratio from 0.3 to 2.8, in the hot humid city of Dhaka, Bangladesh, in summer. Also, the aspect ratio and the street orientation determines the time of exposure to direct solar radiation and the occurrence of extreme heat stress (Ali-Toudert and Mayer 2006). Shashua-Bar (2006) indicated that the thermal effects of built form, vegetation and colonnades, in streets and in courtyards depend on the envelope ratio (i.e.,), the overall geometry factor. Johansson and Emmanuel (2006) analyzed the influence of street canyon geometry on the outdoor thermal comfort in Colombo, Sri Lanka and the study revealed that the differences in air temperatures were higher during the day, especially in the afternoons when compared to the night and a maximum difference of 7^{o}C was found between sites.

It is difficult to predict the actual thermal sensation of humans because of the varying climatic conditions in the outdoors and the changes in the personal factors such as the clothing and activity level. PET – a universal outdoor thermal comfort index (Jendritzky et al 1990, Matzarakis et al 1999), is defined as the "Physiologically Equivalent Temperature at any given place (outdoors or indoors) and is equivalent to the air temperature at which, in a typical indoor setting, the heat balance of the human body (work metabolism 80 W of light activity, added to basic metabolism; heat resistance of clothing 0.9 clo) is maintained with core and skin temperatures equal to those under the conditions being assessed" (Mayer and Hoppe 1987).

The field of research pertaining to outdoor thermal comfort conditions especially at the street level is relatively new. Matzarakis and Mayer (1998) investigated the thermal component of different urban microclimates in Freiburg, Germany and found that the heat stress levels of the human beings depend mainly on the shading effects and clothing factors. Ali-Toudert et al (2005) found that the heat stress in unobstructed locations is high, when compared to sheltered urban sites in Beni-Isguen, Algeria. Ali-Toudert and Mayer (2006) found the dependence of thermal comfort on the design of the street, including geometry, orientation and other design strategies, such as the galleries and horizontal overhangs. Gulyas et al (2006) examined the outdoor thermal comfort conditions in the complex urban environment of Szeged, Hungary using the RayMan model and found a difference of 15^{o}C to 20^{o}C in the PET index due to the radiation differences in sites that were shaded differently by buildings. Emmanuel and Fernando (2007) insisted that the mitigation strategies adopted by urban designers should be based on human comfort (determined by both MRT and air temperature), rather than on simply attempting to control air temperature alone. Lin et al (2010) indicated that low SVF and sufficient shading with tress and buildings can improve the thermal comfort during summers. Bourbia and Boucheriba (2010) highlighted the importance of street design in Constantine-Algeria and found a difference of 3–6^{o}C in air temperatures between the streets with varying geometry. Also, the wind speed reveals a significant impact in the relationship between the MRT and the SVF, even though solar access has a strong relationship with SVF than the wind speed (Kruger et al 2011). The study on the seasonal effects of urban street shading by Hwang et al (2011) revealed that shading effects provided different thermal sensation at different seasons and suggested that improvement of comfort conditions in urban streets should be based on the requirements of seasonal shading levels. Amirtham et al (2011) found that the differential heating which occurred due to the different aspect ratios of the street canyons resulted in different climatic conditions in urban built forms.

Studies relating to the impact of urban geometry on human comfort conditions in India are very few and deals mostly with indoor comfort conditions. Chowdhury and Ganesan (1983) identified that physiological strain over most parts of India is due to the heat and accounts for nearly 80% of the stress. Jauregui (1991) characterized different human climate conditions in the tropical cities using the Effective Temperature index (an index of heat stress on the human body) and found that the comfort levels are significantly reduced while walking on the streets due to the high radiation levels. Thus, this study attempts to contribute to the understanding of the relationship between built form, air temperatures and comfort conditions in an institutional campus in the hot humid city of Chennai, India.

AREA OF STUDY

Sathyabama University is an institutional campus in the suburbs of Chennai experiencing hot humid climate. The maximum air temperatures during summer (May and June) varies between 38°C and 42°C and the minimum air temperatures during winter (December and January) varies between 18°C and 20°C. The average monthly relative humidity ranges from 63% (June) to 80% (November) and the vapour pressure varies between 22.6hpa and 32hpa.

The institution houses several academic blocks of varying street geometry enclosing open spaces and streets for interaction. Five different locations in the campus were selected considering various parameters such as the percentage of vegetation, orientation of streets and canyon geometry (H/W ratio). The street geometries identified for the study ranged from 0.5 to 2 (H/W ratio). The thermal properties of the built surfaces were similar in all locations. Figure 1 shows the measurement locations in the campus and Table 1 shows the characteristics of the selected locations.

Figure 1 Measurement locations in the Campus

METHODOLOGY

The impact of built geometry on microclimatic conditions was assessed through field measurements. The air temperature and relative humidity data were measured continuously on an hourly basis using HOBO dataloggers (HOBO U20 Temp/RH) in the selected locations. The wind speed and the cloud cover data from the Nungambakkam Meteorological station were used for the study as the above data could not be measured at study area. Microclimatic variations of the selected locations were analyzed for a hot day in May (summer). The influence of urban morphology on outdoor thermal comfort conditions is calculated through the most commonly used outdoor thermal comfort index - Physiologically Equivalent Temperature (PET) (Matzarakis et al 1999, Emmanuel 2005, Johansson 2006). RayMan Pro model (Matzarakis et al 2007, 2010) has been used to calculate Physiologically Equivalent Temperatures as it takes into consideration all environmental factors influencing thermal comfort. The model calculates the radiation fluxes within the complex urban environments based on the time of the day and year, meteorological parameters (air temperature, humidity, degree of cloud cover), surface morphological conditions (geographical locations, building geometry, albedo of the surrounding surfaces, sly view factor) and personal data (age, height, weight, clothing, activity level.

Table 1. Characteristics of the Measurement Locations

Site	Plan	Section	SVF	H/W
Location 1			0.467	1
Location 2			0.623	0.5
Location 3			0.240	2
Location 4			0.362	0.5
Location 5			0.271	1.67

The 200m X 200m grid along with their shadow patterns and Sky View Factor (SVF) are shown in Figure 2. Also, a questionnaire survey on thermal sensation in the selelcted locations was conducted to study the subjective response of students on outdoor thermal environment. The subjective response of respondents and PET Index were compared to identify the appropriate built geometry for thermally comfortable environment.

RESULTS AND DISCUSSIONS

The influence of urban morphology on outdoor thermal comfort conditions were analyzed with respect to parameters such as orientation, street geometry (H/W ratio) and percentage of vegetation. The air temperature and PET variations at five selected locations are shown in Figure 3. Mayer et al (2009) states that the atmospheric conditions are modified by the urban processes and built form; and results in increase or decrease in ambient air temperatures which is a function of various parameters such as weather, time and day of the year, street geometry and built structure. Amongst the five locations in the campus, location 1, 3 & 5 are oriented in the N-S orientation and location 2 & 4 are oriented in the E-W direction.

Air Temperature and PET Analysis

The air temperature and PET were analyzed with reference to orientation, street geometry and percentage of vegetation of selected locations.

Orientation, The selected streets in the campus were oriented in the N-S and E-W directions. The air temperatures in the E-W oriented street at location 2 were higher than N-S oriented streets (location 1,3,5) through out the day (8.00hrs to 16.00hrs). Even though location 4 had similar orientation and

Figure 2 Calculated Shadow Patterns and SVF at various locations using RayMan Pro 2.1

street geometry as that of location 2, temperatures were almost similar to that of N-S oriented streets except at 14.00hrs which could be attributed to the shading of the instrument. The variation in the air temperatures with resepect to orientation (E-W vs N-S) were higher at during daytime when the sun's radiation is at the maximum ranging from 1.47^{o}C at 10.00hrs to3.7^{o}C at 14.00hrs. The outdoor comfort conditions with respect to PET values also varied from 2.1^{o}C at 10.00hrs to 6.6^{o}C at 14.00hrs. The study also found that PET values were lesser than air temperatures at 6.00hrs and 18.00hrs thus reinforcing the fact that absence of direct solar radiation increases the comfort conditions i.e., thermal sensation. The PET values were as less as 3.39^{o}C when compared to air temperatures at 6.00hrs.

Vegetation, Except locations 4 & 5, the absence of vegetation in other locations nullifies the cooling effect through shading and evapotranspiration. Even though the street geometry and orientation

(E-W) of locations 2 & 4 were same (H/W = 0.5), their thermal recordings varied upto 3.28^{o}C at 14.00hrs, due to presence of vegetation at location 4. The N-S oriented streets at location 1 & 5, also experienced significant thermal differences of about 2.3^{o}C at 14.00hrs, attributed mainly due to the presence of significant vegetation at location 5.

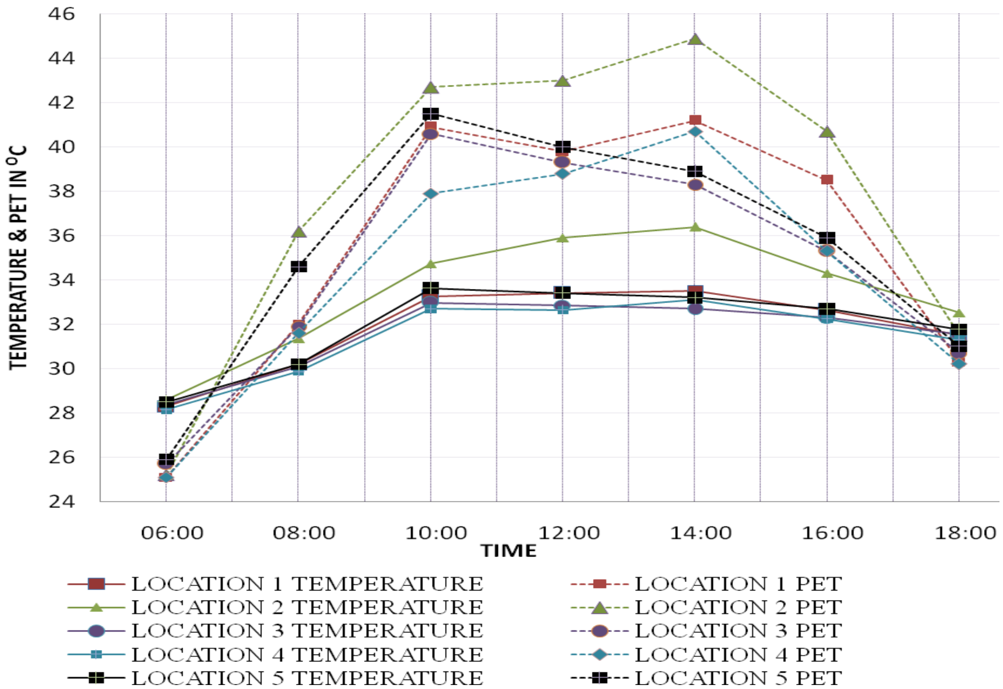

Figure 3 Air temperature and PET variations at various locations

Street geometry, The variations in air temperatures with respect to height to width ratio increases gradually from 8.00hrs (1.1^{o}C) to 14.00hrs (3.7^{o}C) and reduces from 18.00hrs reaching almost similar temperatures at 6.00hrs. The H/W ratio is inversely proportionate to air temperatures and PET values, i.e., higher the H/W ratio lesser the air temperatures and PET values. Thus the study reveals that narrow streets are comfortable during daytime due to internal shading of buildings in hot humid climates, thus improving the outdoor comfort conditions.

The comfort conditions expressed by PET values were higher than the air temperatures by 8.5^{o}C during daytime (8.00hrs to 16.00hrs) attributed to the presence of intense solar radiation. In the absence of direct solar radiation, the human thermal sensations represented by PET values were lesser than the air temperatures upto a maximum of 3.39^{o}C lesser than the air temperatures. Analysis also revealed higher variation in PET values when compared to temperature differences at location 2 & 3 at 14.00hrs. For a temperature difference of 3.7^{o}C between location 2 & location 3 at 14.00hrs, PET differences of 6.6^{o}C existed at the same locations. This indicates that even slight variation in air temperatures can have a significant impact in the comfort conditions (PET) during daytime.

Location 2 experienced the maximum temperature and PET values at 14.00 hrs owing to its E-W orientation of the street, H/W ratio of 0.5, SVF of 0.623 and absence of vegetation. Also the concrete pavements and absence of shading by trees and buildings added to the discomfort. Almost all the five locations were above the upper limit of discomfort of 33^{o}C as stated by Ahmed (1994), during daytime (between 07.00 hrs and 17.00hrs). The temperature in the PET index increases with the increase in ambient air temperatures and the difference between the same is as high as 8.5^{o}C at 14.00hrs. At 6.00hrs the PET was lesser than the air temperature by 3.05^{o}C at location 4 which recorded the minimum temperature. This clearly reveals that the outdoor thermal comfort index has a significant impact with direct solar radiation. PET index during night time was comfortable and was well within the upper limit of comfort (33^{o}C) and was also lesser than the ambient air temperatures.

Questionnaire Survey and PET Analysis

The questionnaire survey revealed that the respondents experienced the heat stress during daytime as the PET varied from 34.6^{o}C to 44.9^{o}C between 8.00hrs and 16.00hrs. The thermal sensation at locations 3 & 5 was almost tolerable at 14.00hrs due to internal shading by buildings and trees. The N-S orientation of these locations had a significant impact on the thermal sensation. Location 1 which was also oriented in N-S direction experienced higher discomfort due to its street geometry with SVF of 1. The thermal perception of the respondents was too warm at locations 1 & 2 due to the absence of internal shading. Also the reflective nature of the abutting buildings had a significant impact on the thermal sensation in the above locations. In general the thermal perception at locations 1, 2 & 4 were not satisfied and the users experienced heat stress. The overall conditions inside the campus are acceptable for the users near the locations 3 & 5 due to the N-S orientation and the presence of vegetation, thus providing a tolerable environment at these locations.

CONCLUSION

The air temperature and the PET trends in the campus revealed that the nights were comfortable when compared to day. During daytime, all the streets were uncomfortably hot with the PET values well above the upper limit of the comfort zone. As the daytime comfort was found to have a significant correlation with the street geometry (SVF), presence of vegetation and orientation, the study indicates the significance of improving the daytime comfort in the campus, by stipulating appropriate built geometry and orientation in the new developments in campus. Also if the concept of internal shading is adopted in the existing built form, it can improve the comfort conditions to a significant level. Based on the study, recommendations pertaining to some of the aspects of built form have been suggested to improve the outdoor thermal comfort conditions at the campus.

- N-S oriented streets are comfortable when compared to E-W orientation. If E-W orientation is essential in the design, then appropriate shading of streets through shaded corridors, projected balconies, and vegetation can improve the pedestrian comfort considerably in campus.
- Shading through vegetation significantly reduced air temperatures and PET values during daytime irrespective of the orientation.
- Narrow streets oriented in the N-S direction reduced the heat stress during daytime as they reduce the time of exposure to direct intense solar radiation. Also the internal shading of buildings accelerated the comfort conditions at pedestrian level.

The Ability of Current Rating Tools to Guarantee Sustainable Successes: Balance and Perspective

Bart Janssens

Faculty of Design Sciences – University of Antwerp, Belgium

bart.janssens@uantwerpen.be

ABSTRACT

The use of assessment and rating tools by design teams is increasing. In a parallel development, demonstration projects aimed at improving sustainability in building are being increasingly endorsed. This paper addresses the question of whether projects that have been assessed and rated are necessarily worthy of designation as 'sustainable successes', leading to enhance the reproducibility of up-front sustainability measures, ultimately broadening the base for sustainable building.

Within the field of contemporary European sustainable group housing, actual projects that have been assessed and rated are explored and positioned relative to recognised demonstration and best practice projects. Focus lies primarily on projects supported and rated by the BREEAM (Building Research Establishment Environmental Assessment Method). In order to increase the reliability, outcomes are verified by cases rated with other multi criteria sustainability tools. The study is conducted from the perspective of the architect-designer, focusing on actual sustainable design measures and features as comparative parameters with reference to the two most tangible pillars of sustainable building (i.e. 'Planet' and 'People').

The results of this illustrative study indicate that the assessment and rating tools that are currently available cannot guarantee full success with regard to sustainability. Projects that have been assessed and rated do not necessarily constitute 'best-practice projects'. The analysis raises several issues regarding sustainability tools and suggests perspectives with regard to 'design attitude'. Promising perspectives involve appropriate and integrated design measures, a conceptual approach and, most importantly, architectural solutions.

INTRODUCTION

Once they realise the necessity of an integral approach to sustainability, architect-designers are faced with a complex task. Multi-disciplinary actors in the construction industry are undertaking frantic efforts to facilitate this task by focusing on the development of assessment and rating tools. The use of these tools is increasing, not only as a means of evaluating buildings with regard to their sustainability, but also as a design supporting tool (Abdalla, Maas, Huyghe and Oostra, 2011). Parallel to the development of such incentives, multiple authors and public organisations are endorsing the importance of demonstration projects in the quest for more sustainable building (Buijs & Silvester, 1996) (Feminas, 2004) (Van Hal, 2000).

Two issues are relevant in this regard. First, the outcome of an assessment is highly dependent upon the set of components and indicators incorporated into the selected tool. For this reason, some projects might not cover the full scope of sustainability. Second, 'demonstration and best-practice projects' are receiving considerable attention in both the popular media and the scientific literature. Nevertheless, their performance with regard to sustainability has rarely been tested according to the most prominent and widely used multi-criteria assessment methods. Combined with the increasing general interest in sustainability tools, this could mortgage the recognition of the sustainability value and benefits that such projects offer.

This study focuses on actual projects that have been assessed and rated according to the BREEAM (Building Research Establishment Environmental Assessment Method). The main objective of this chapter is to explore and position these projects relative to renowned European demonstration and best-practice projects. This positioning can provide a preliminary answer to the question of whether projects that have been assessed and that have achieved high ratings are necessarily worthy of designation as best-practice projects that intended to enhance the reproducibility of up-front sustainability measures, ultimately broadening the base for sustainable building. The analysis raises several issues and suggests perspectives with regard to 'design attitude'.

METHODOLOGY

The research and argumentation of this study can be characterised as a cross-case comparison in tabular form. Case-study methodology is appropriate for investigating contemporary phenomena (e.g. sustainable building) (Yin, 1994). In order to increase reliability, multiple projects are considered. The study is conducted from the perspective of the architect-designer, focusing on actual sustainable design measures and features as comparative parameters with reference to the two most tangible pillars of sustainable building (i.e. 'Planet' and 'People').

The literature contains no consensus regarding the content and naming of sustainable design measures and features. A self-compiled set was therefore made for this study. The determination of these comparative parameters, the analysis of the comparison and the formulation of issues and perspectives is based on empirical observations, as well as on a review of literature regarding selected demonstration and best-practice projects. These resources are supplemented by a tentative theoretical description of sustainable building in the European context. This abductive reasoning can be seen as an iterative process between the collection and analysis of empirical material and the study of theory in literature (Feminas, 2004).

Assessment and rating tools are intended to evaluate performance related to various aspects of sustainability. This study examines projects that have been assessed and rated according to the most prominent and most widely known and used system in Europe: BREEAM ("BREEAM Meest Toegepaste Certificering"). In this system, credits are awarded in nine categories and added together to produce a single overall score, positioned along a scale ranging from 'Pass', 'Good' and 'Very Good' to 'Excellent' and 'Outstanding'.

As suggested in the literature, demonstration projects should meet the following conditions: repeated evaluations, an open and public character and the intention to act as a demonstration project from the beginning, as well as a special character (Buijs & Silvester, 1996) (Van Hal, 2000) (Keating & Peach, 1989).

The projects addressed in this study were selected from within the field of grouped housing in Europe. Specific features of these projects (e.g. overlapping scales, collectivity) contain embedded aspects of sustainability, as well as opportunities for realising additional sustainability measures, although they are also accompanied by critical barriers.

From the projects that have been assessed and rated by the BREEAM, the following were selected for this study: 'De Balk van Beel' in Belgium and 'Sanderstead Road' in the United Kingdom. Both are compared according to the self-compiled set of comparative parameters. Another project featuring typological similarities to 'De Balk van Beel' was added to the research in order to enhance the specificity of the comparison and to illustrate the stated perspectives: 'Kronsberg' in Hannover (Germany).

This study, derived from an ongoing doctorate dissertation (Janssens, ongoing) is illustrative and primarily representative of the selected case studies and of the assessment and rating tool. The methodology of using comparative parameters, based on Feminas (2004), is considered relevant, although it is not the only approach possible. The set of comparative parameters is neither exhaustive nor definitive. Finally, the perspectives suggested within the specific theoretical framework should be seen as one of many possible solutions.

IDENTIFICATION OF SELECTED ASSESSED AND RATED PROJECTS

The 'De Balk van Beel' involves the pilot construction within an ongoing new neighbourhood development ('Tweewaters') in Leuven. The project comprises four upper floors containing 101 different housing units. The ground floor contains shops and services for the neighbourhood.
Upon completion of the design, the project was assessed using the 'International Bespoke 2010' version of the BREEAM, which resulted in an 'interim design stage' certification. The design achieved a score of 87.81%, which corresponds to an 'outstanding' rating. The development achieved 100% of the available credits in the categories of 'Management', 'Health & Wellbeing' and 'Land Use & Ecology', and it scored over 90% in the categories of 'Energy' and 'Transport'.

The new housing development 'Sanderstead Road' is located on a derelict brownfield in the London Borough of Croydon. It comprises a three-storey block of 38 one-bedroom and two-bedroom flats, partly constructed over three new ground-floor commercial units, with two blocks of three-storey semi-detached, four-bedroom houses in the courtyard area. Assessment using the 'EcoHomes 2006' version of the BREEAM resulted in an 'interim design stage' certification. The overall score of 75.41% corresponds to an 'excellent' rating. The project team performed well across all categories, particularly in relation to 'Materials' and 'Management'.

Figure 1 Selected cases for the cross-comparison: left 'De Balk van Beel'; right 'Sanderstead Road'. Source: Bart Janssens

CROSS-CASE COMPARISON

Table 1 provides a tabular comparison of sustainable design features and measures of the selected BREEAM projects with exemplary practices in Europe. Data are subdivided into two categories: 'embedded sustainability features' and 'added sustainability measures'. The first category covers features that are at least partially inherent in the field of grouped housing. The second category includes measures added through some level of deliberate effort, either at the neighbourhood level or at the building level.

A description of the complete list of comparative parameters and a thorough discussion of the comparison is not possible within the limited length of the paper. As this comparison represents the basis of the argument of this research, it will be discussed and documented in depth during the oral presentation.

Table 1. Cross-case comparison of sustainability design features and measures.

	Exemplary practices		BREEAM projects	
	Prevailing demonstration projects	'Kronsberg'	'De Balk van Beel'	'Sanderstead Road'
Embedded sustainability features				
High density (≥ 50 units per net hectare)	●	●	●	●
Collective meeting spaces	●	●		
Extensive range of housing types	●	●	●	●

Implemented measures	●			
Postponed or expired measures	○			

ANALYSIS OF THE RESULTS FROM THE CROSS-COMPARISON

As revealed in the cross-case comparison, the selected BREEAM projects lack most of the sustainability features that they are assumed to include. Little or no attention is paid to the intermediate scale or to the collective or semi-public space. With regard to the list of additional measures, the projects incorporate few, if any bioclimatic design principles, while other measures exceed most of the project examples contained in the cross typology (e.g. real-time energy-monitoring systems and home-delivery boxes). Many similarities can be observed with regard to low energy performance and provision of energy-efficient and water-efficient appliances.

The measures prevailing in the demonstration projects and the BREEAM projects differ in terms of their overall character. While most demonstration projects assign priority to tangible, architectural solutions, the BREEAM projects tend to focus more on relatively technological measures (e.g. open storm-water systems versus storm-water infiltration units; wind cowls versus mechanical systems).

The selected BREEAM projects show only limited aspects of social sustainability. The lack of embedded sustainability features and the nature of the sustainability measures applied result in the absence of 'people features'. The assessment of projects with a tool containing components and indicators that emphasise a more social approach to sustainability (or even a better-balanced set of components) would change performance in terms of sustainability.

As demonstrated in comparative studies, most tools have their own content, areas of focus and methods (Fowler & Rauch, 2006) (Saunders, 2008). The outcome of an assessment depends heavily upon the set of components and indicators which are included in the selected tool. Yet included aspects of sustainability are listed and rationally tackled in the hope of achieving intended desired rating. In many cases, design teams resort to technological and even highly innovative measures. This can have two consequences. First, such strategies increase investment costs. Second (and often related to the first consequence), there is a true risk that measures will be postponed or will even expire during the further design and/or construction process. The analysis of the 'De Balk van Beel' reveals that certain key measures have been cancelled (e.g. electronic butler service) or transferred to future neighbourhood developments (e.g. combined heat and power plant, recycling station, kitchen gardens) (Janssens, 2013). Other measures are mentioned only as options (e.g. storm-water infiltration unit) or seem to be to innovative (e.g. home delivery boxes). The BREEAM score obtained during the design phase hence does not necessarily guarantee the building's final sustainability performance. Particular measures can prove to have different outcomes during the construction and usage phase. This finding corresponds to results reported by Ding (2007) and by Abdalla et al (2011).

By promoting designs oriented towards solving single problems, assessment and rating tools apparently steer architects/designers towards less than optimal measures. Creativity comes at the expense of easy 'add-on' technological solutions, thus eliminating opportunities and inspiration for liveable, creative and efficient living and working environments. This single-problem approach to sustainability is likely to result in sustainability decay, as illustrated by the BREEAM projects addressed in this case study.

PERSPECTIVE AND ILLUSTRATIVE VERIFICATION

Gaining efficiency and decisiveness will require a shift in focus from checklists and performance criteria to practical sustainability measures, which are more appropriate for architect-designers. The 'design attitude' of architects/designers with regard to sustainability should shift from measures intended to resolve single problems towards multiple integrated measures, concepts and architectural solutions. The practice of finding 'promising combinations' is the common ground for both sustainable transition and sustainable design (Tjallingii, 1996). Thinking in terms of design combines possible solutions from disciplines that are fundamentally different (Cross, 2006) (Van Bakel, 1995).

Measures are deliberate and distinct decisions intended to fulfil specific requirements and to achieve desired features. Measures that serve several requirements can increase efficiency, diminish (or even eliminate) objections to implementation and reduce the risk of postponement and/or expiration. As described by Janssens and Van Dorst (2012), 'Beneficial Pattern Measures' (BPM) are building-design measures that have positive effects on multiple targets. Applied to sustainability, BPMs aim to satisfy both environmental ('Planet') and social ('People') pillars/components/indicators (Figure 2). Common BPMs in European demonstration projects include 'glazed balconies' and 'greenhouses', often as components of the lighting, heating, cooling and/or ventilation design. With regard to the 'People' aspects of sustainability, these measures enhance social contact between owners and passersby, in addition to their ability to enhance social control, create potential spaces for identification and expansion, and provide a transitional zone between public and private spaces. These primarily 'Planet'-oriented measures also address a wide range of 'People' aspects.

Despite the use of BPMs, individual sustainability measures cannot address the full range of sustainability issues, and they often generate sub-optimal solutions. Multiple measures must be combined in a mutually reinforcing manner, resolving any disadvantages or bottlenecks. 'Beneficial Multiple Pattern Measures' (BMPM) combine several promising BPMs into successful sustainability packages. In many cases, the BPMs that are outlined (e.g. 'glazed balconies' and 'greenhouses') are replaced by simplified versions (e.g. 'large windows'). In the demonstration project 'BO-01' in Malmö (Sweden), an 'open storm-water system' was placed in front of the buildings, broadened and supplemented with 'plants' near 'large windows' (Figure 3). In addition to being an interesting and attractive feature in an urban context, this solution is able to regulate privacy. The creation of a distance and the presence of plants avoid the need to cover the windows, thus preventing them from losing their previously stated potential for serving important functions.

Given the context-specific nature of every assignment, BMPMs must be composed and combined into an integrated approach with regard to all predefined requirements, terms and conditions. A conceptual approach is crucial when working with 'integrated multiple measures'. The development of concepts prevents inefficiencies in later design stages, and it increases the likelihood of sustainable success in a cost optimal way (Rovers, 2008). Concepts facilitate the successful implementation of measures by focusing on the achievement of several objectives in an integrated manner (Figure 2). This can be defined as a 'Beneficial Pattern Concept' (BPC).

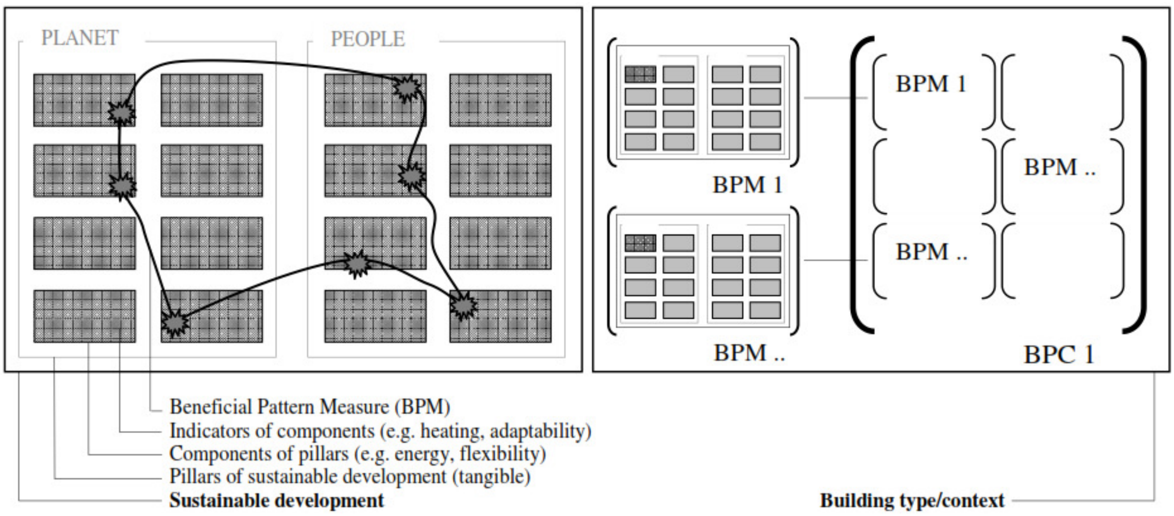

Figure 2 Figurative representation of 'Beneficial Pattern Measures' (BPM) and 'Beneficial Pattern Concepts' (BPC). Source: Bart Janssens (2013)

The ‘Kronsberg’ project contains architectural solutions within a strong conceptual approach. Dwelling units were placed back-to-back, facing east and west, and separated by a covered atrium (Figure 3). During a test case for research by design, the atrium was optimised with regard to sustainability. It was also implemented and developed into a full BPC (‘the bioclimatic street’) for a typology resembling that of ‘De Balk van Beel’. Verification of architecture and sustainability revealed that the concept is effective and efficient, coupling aspects of sustainability (e.g. water, ecology, energy, health, comfort, social value and architectural design) with regard to both environmental and social sustainability.

Figure 3 Left: example of a ‘Beneficial Multiple Pattern Measure’ (BMPM) in ‘BO-01’ in Malmö: ‘open storm water system’ – ‘plants’ – ‘large windows’. Right: example of a ‘Beneficial Pattern Concept’ (BPC) in ‘Kronsberg’ in Hannover: ‘the bioclimatic street’. Source: Bart Janssens

The development of new measures and the optimisation of existing measures and concepts could be stimulated against the background of a theoretical and practical framework based on knowledge concerning particular sustainability measures (e.g. scope, promising combinations, deferability, adaptability, added ability). Architect-designers can indulge their creativity, thereby broadening the base for sustainability, ultimately generating a sustainable transition for the built environment.

FINALIZING REMARKS

Outlook verification: In order to increase the reliability, outcomes will be verified by other cases, which will be discussed and documented in depth during the oral presentation. Research will be based on empirical performance data derived from occupied buildings. Within the BREEAM assessed and rated projects, ‘Futura’ (Zoetermeer, The Netherlands) will be investigated. Within other multi criteria sustainability tools, following projects will be reviewed: ‘Cortinghborg’ (Groningen, The Netherlands) rated by ‘GPR Gebouw’; ‘Eco-Life’ (Kortrijk, Belgium) rated by ‘Vlaamse Maatstaf voor Duurzaam Wonen en Bouwen’; ‘Les Dominos’ (Lyon, France) rated by ‘HQE’.

Future research and discussion: There are a number of future research and discussion topics concluded to be relevant. First, in order to prevent the introduced BPMs, BMPMs and BPCs in becoming as impenetrable and convulted as the ticked boxes of most multi criteria assessment and rating tools, a clear and ‘architect-designer friendly’ knowledge structure is needed. Second, when setting out such knowledge structures it is most important to rely on factual evidences in order to avoid preconceptions. Because of the often occurring discrepanties between the results of assessments and actual performances of designs/buildings, research should study actual ‘real-life’ buildings more closely. Sustainability tools should learn and improve from past projects. Third, the focus in next steps in the development of assessment and rating tools is plural: the improvement of methods of evaluation and shortlisting of relevant and appropriate criteria for each project, the recognition and accountance for synergies between performance criteria, a more holistic audit (full sustainability scope) and monitoring approach, etc. In tackling these issues focus should be on architectural and contextual measures and issues in order to encourage integrated 'People-Planet solutions'. A system thinking approach between assessment tools and knowledge structures, i.e. matching evaluation criteria and e.g. BPMs, is believed to be promising.

Preliminary conclusion: This illustrative study on selected BREEAM projects demonstrates that current assessment and rating tools cannot guarantee complete success in the area of sustainability. Projects that have been assessed and rated do not necessarily constitute 'best-practice projects'. Most current tools have a unilateral focus on checklists and/or performance criteria for a selection of sustainability aspects, thereby encouraging the practice of designing to solve single problems. In many cases, this can lead to a single orientation with regard to sustainability, possibly leading to sustainability decay. Tools can facilitate success in sustainability, on the condition that their constituting components and indicators cover the full scope of sustainability, and provided that architect-designers are aware that sustainability arises from engagement with the complexity of the situation, and not from checklists. A theoretical and practical illustrative framework with regard to an 'integrated multiple design attitude' indicates that, regardless the use of sustainability tools during or after the design process, the keys to success in sustainability include knowledge about and the implementation of appropriate and integrated design measures, a conceptual approach and, most importantly, architectural solutions. Research is needed on a suitable knowledge structure and the linkage with optimized assessment and rating tools.

ABSTRACT

In rural Japanese cities, many old and densely populated urban districts have been replaced by high-rise residential buildings because of urban redevelopment. High-rise building affects the sunshine conditions and wind environment of the surrounding areas. These problems have been already discussed; however, it is rarely discussed how high-rise buildings affect the outdoor and indoor thermal environment of their surroundings. Particularly, shading is a serious problem in winter because it makes the outdoor environment colder and increases the energy consumption for heating of adjacent buildings in addition to daylight shortages.

The shading effect of a high-rise building on the outdoor and indoor thermal environment in winter is simulated by a 3D CAD-based thermal environment simulator. As a result of the simulation, shading effect by high-rise building at noon extends widely to the area apporoximately 200m away in the north, but the 7 °C difference in the mean radiant temperature in the shaded area is caused by the surrounding space geometry and material. Also, in the northern or western street of high-rise building, many shops exist and their façade with large windows make the shading effect on the building heat load more remarkable. The building heat loads of these buildings are more than 30% larger than that in the case when the high-rise part is removed.

INTRODUCTION

In rural Japanese cities, many people used to live in densely populated urban districts near train stations with many prospering businesses nearby. However, because of decreasing district population and development of suburban areas, many district buildings were vacated and replaced by high-rise residential buildings, and many businesses closed.

High-rise buildings cause problems such as preventing access to sunlight, and creating strong wind conditions, and affect the landscape. When constructing high-rise buildings in Japan, the building height is regulated by the Building Standards Law. The law has a regulation about indexes such as duration of solar shading and sky factor from the viewpoint of access to sunlight. Moreover, in several cities, environmental assessments are required when the height of high-rise buildings is greater than 100 m. For these assessments, wind conditions are simulated using CFD (RANS).

As previous studies, Saito (2003) researches the effect of high-rise building on the illuminance and sky factor on the surroundings. Also, Curreli (2011) researches solar access in densely built urban environments. However, it is rarely discussed how high-rise buildings affect the outdoor and indoor thermal environment of their surroundings. As mentioned above, shading is a serious problem in winter. In particular, shading by high-rise building makes the neighboring outdoor environment colder, and increases the energy consumption for heating.

This study reveals the shading effect of a high-rise building on the outdoor and indoor thermal environment in winter using numerical simulations. The building heat load is calculated considering the effect of the outdoor thermal environment. An urban district with and without high-rise buildings are reproduced using the 3D CAD system and then compared.

METHODOLOGY

Target urban district

The target district is in Tsuchiura city, which is approximately 60 km from Tokyo in the north, and is located in the city center near Tsuchiura Station. The district has high pedestrian traffic and several shops. Low-rise shops and residential buildings were closely built, and commercial and high-rise residential buildings were first built in 1997. Furthermore, parking lots have replaced many of the original houses and shops. The height of the high-rise building in the target district is 109 m, with a north-facing open space for events. The high-rise building affects the thermal environment of the surrounding outdoor spaces, particularly the thermal radiation environment of sidewalks and parking lots. Moreover, it affects the thermal environment of the surrounding buildings, and the shading owing to the high-rise building increases the energy consumption for heating.

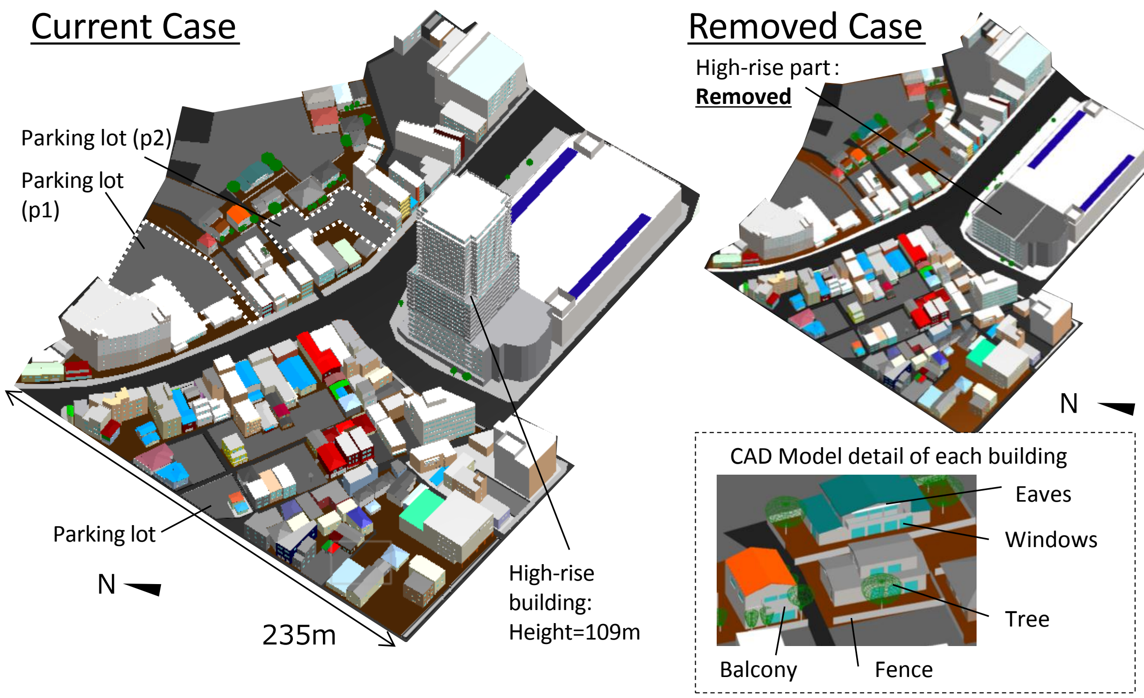

Figure 1 3D CAD model of the target urban district

Simulation method

In order to reveal the effect of shading owing to the high-rise building on the thermal environment of outdoor and indoor spaces, we analyzed the thermal environment in the target urban district using an in-house 3D CAD-based thermal environment simulator (Jiang H. et al., 2009; Asawa T. et al., 2008).

We collected spatial geometry and material data for 2009 and constructed 3D CAD models of the site at a scale of 1:500 (Sato R., et al., 2009). Two models were constructed; the first (current case) reproduces the current state, whereas the second (removed case) reproduces the state when the high-rise part is removed from the high-rise building.

Next, we calculated the outdoor surface temperature distribution in the target district under clear sky conditions in winter using the 3D CAD-based thermal environment simulator (Weather condition: Fig. 2). First, the 3D spatial forms of buildings, trees, and other structures and the 2D ground surfaces are divided into voxel mesh grids (mesh size: 400 mm). Then, the outdoor surface temperature for each grid was determined by solving the unsteady-state 1D heat balance equation in the vertical direction of the surface. The terms of the heat balance equation are direct solar radiation, sky solar radiation, reflected solar radiation, atmospheric radiation, longwave radiation exchange with surroundings, convective heat transfer, latent heat transfer, and conductive heat transfer. Each radiation is calculated by the ray tracing method, and the convective heat transfer is calculated assuming outdoor uniform distribution for the outdoor air temperature and wind velocity.

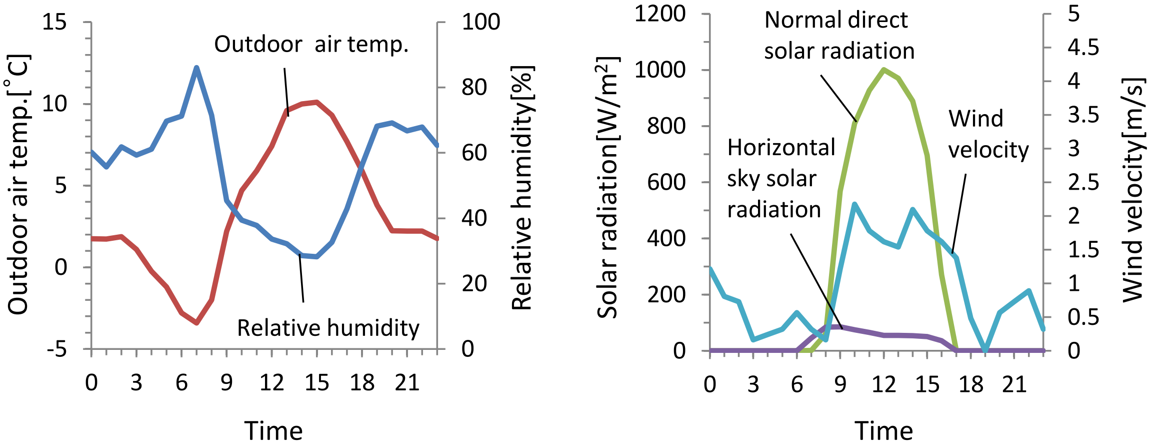

Figure 2 Weather conditions (December 21, a clear sky winter day)

The thermal radiant field in the urban district is evaluated using mean radiant temperature (MRT) at a height of 1.5 m. The MRT is calculated using the following equation, as the shortwave and longwave radiation absorbed by humans. Rhuman is the solar radiation and longwave radiation absorbed on the human surface, calculated from equation (2).

$$MRT[°C] = \sqrt[4]{R_{human}/\sigma} - 273.15 \quad (1)$$

$$R_{human} = a_1 \left\{ \frac{A_p}{S_{human}} \cdot I_d + \sum_{i=1}^{6} W_i (I_{si} + I_{ri}) \right\} + a_2 \sum_{i=1}^{6} W_i \left(L_{object_i} + L_{sky_i} \right) \quad (2)$$

Furthermore, the building heating loads, which consider the effect of surrounding buildings and trees, are calculated using the calculated total radiation and surface temperature distribution on the building's external surfaces. To evaluate the effect of the outdoor thermal environment on the building's indoor thermal environment, each building floor is assumed to be a single room. We further assume that the air-conditioning system is set at 20 °C all day in winter, and the internal heat gains' schedule is based on the standard model of the Architectural Institute of Japan (Architectural Institute of Japan, 1985).

RESULTS AND DISCUSSIONS

Effect on the thermal radiation environment of the outdoor space

Surface temperature distribution

Figure 3 shows the surface temperature distribution in the two cases at 12:15. In the current case, where the high-rise building shades the surrounding urban area, its shade extends 200 m toward the north. Because of the shade, the sidewalk (s1) surface temperature at 12:15 (Fig. 3) is 5 °C, which is 10 °C less than that of the removed case.

On the ground of the parking lot, the surface temperature is different at each spot that is shaded by the high-rise building. Such differences depend on the duration of the shading of the high-rise building. In the current case, the surface temperature of the east side of the parking lot (p1) is 5 °C lower than the rest. On the other hand, the surface temperature of the west side of the parking lot (p2) is greater than 10 °C because the asphalt pavement accumulates heat by solar radiation in the morning.

In some parking lot which is not shaded at 12:15, the cold accumulation owing to the morning solar shading remains on the ground. As a result, the surface temperature at 12:15 in the parking lot (p1) adjacent to the shaded area decreases by 5 °C compared with the removed case. The area where the surface temperature decreases owing to cold accumulation occupies approximately 25% of the parking lot (p1) area.

Mean radiant temperature distribution

Figure 4 shows the mean radiant temperature distribution and surface temperature distribution in the outdoor space shaded by the high-rise building. At the sidewalk (s1), the mean radiant temperature for the current case decreases by more than 15 °C compared with the removed case owing to shading and decrease in surface temperature. In the parking lots shaded by the high-rise building, the mean radiant temperature in the current case also decreases compared with the removed case. However, the mean radiant temperatures of the parking lots differ in the shaded area of current case and the difference is 7 °C. At point X, the mean radiant temperature is 0 °C, which is 7 °C lower than the air temperature.

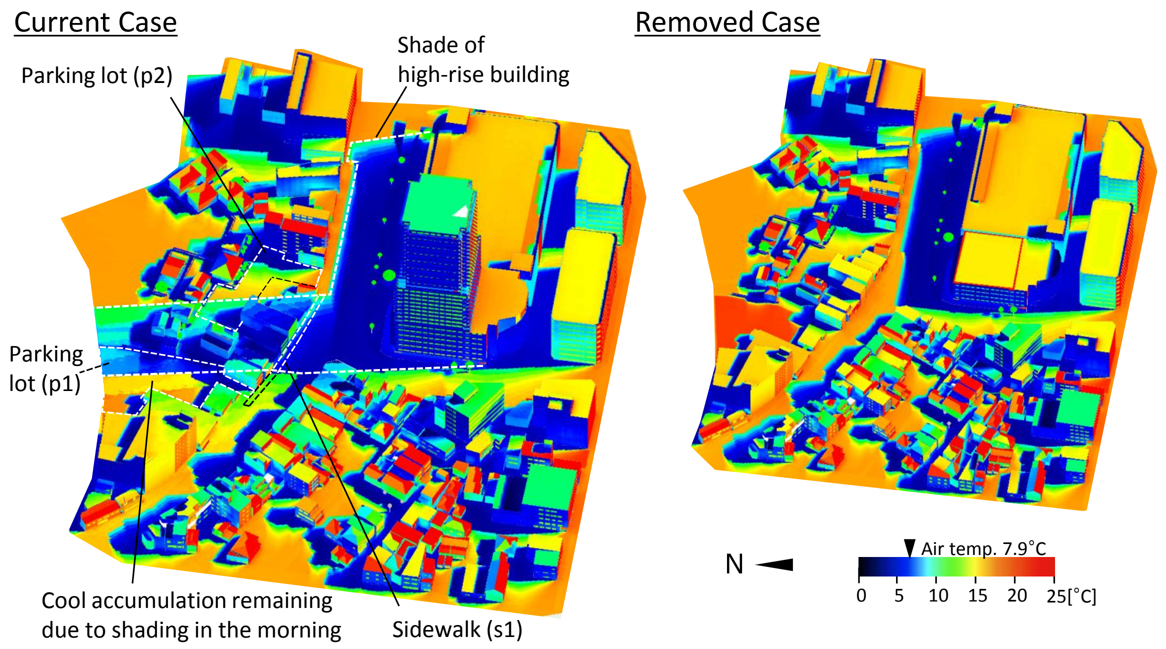

Figure 3 Surface temperature distributions at 12:15

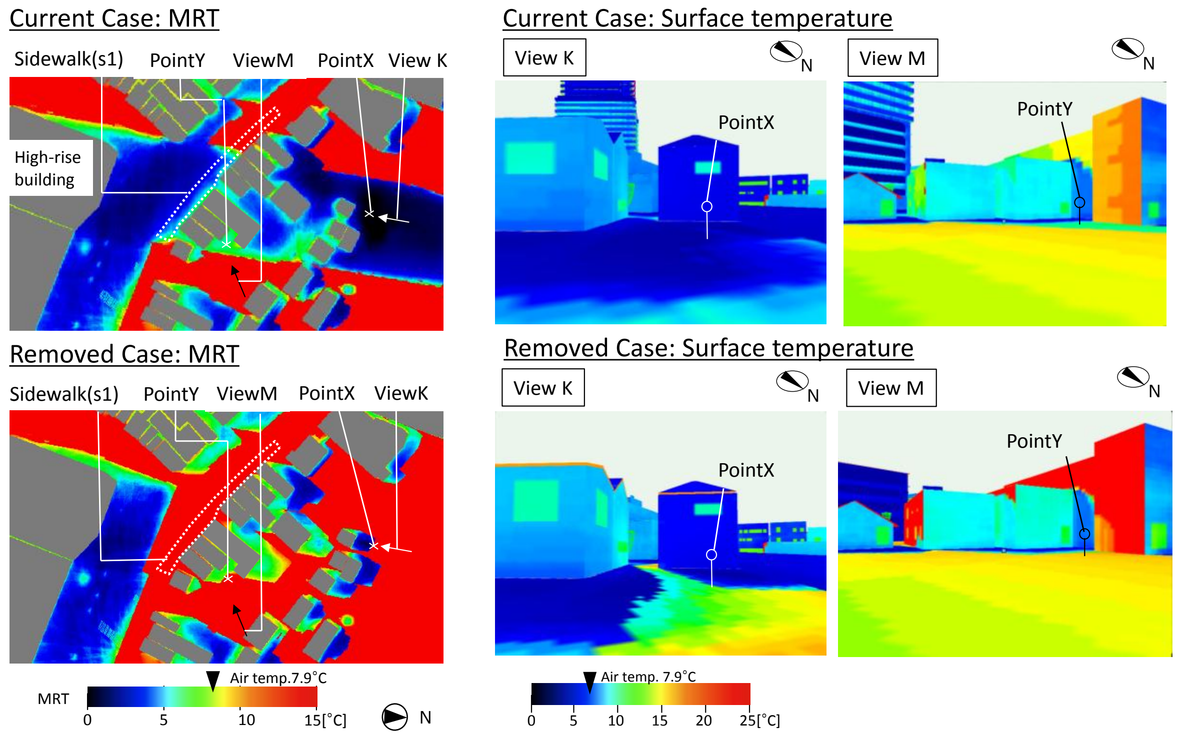

Figure 4 Mean radiant temperature distribution at 12:15 and at a height of 1.5 m, and surface temperature distribution at 12:15 in the outdoor space shaded by the high-rise building.

This is attributed to the ground that is shaded by the high-rise building and the surrounding buildings, and the building wall with low surface temperature (see View K in Fig. 4). On the other hand, at point Y, the ground surface temperature is more than 10 °C higher than that at point X, and the surrounding building wall keeps the surface temperature high owing to heat accumulation (see View M in Fig. 4). As a result, the mean radiant temperature at point Y of the current case is 7 °C higher than that at point X.

Effect on the building heat load

The relation between the daily solar radiation, which is received by the windows, and the heat load of each building is examined to demonstrate the effect of shading by the high-rise building. We focus on the building that is shaded by the high-rise building for more than 1 h and calculate the building heat load. Figure 5 shows the daily solar radiation distribution in each case and the increasing rate map of the building heat load. Figure 6 shows the diurnal change in the solar heat gain and heat load in the buildings. In this district, many buildings have large windows in the southern or eastern facades, which face the street in the north or west of the high-rise building. As shown in Fig. 5, in the building shaded by the high-rise building for more than 2 h, the daily solar radiation on the building southern facade is 5 MJ/day lower in the current case than in the removed case. Hence, these buildings with large windows increases by more than 30% in the heat load.

The shading effect on the building heat load depends on not only the distance from the high-rise building and but also the window location and site conditions. When the building is close to and has no windows facing the high-rise building, such as building (a), the rate of increase in the building heat load is within 5% despite being shaded by the high-rise building for more than 2 h.

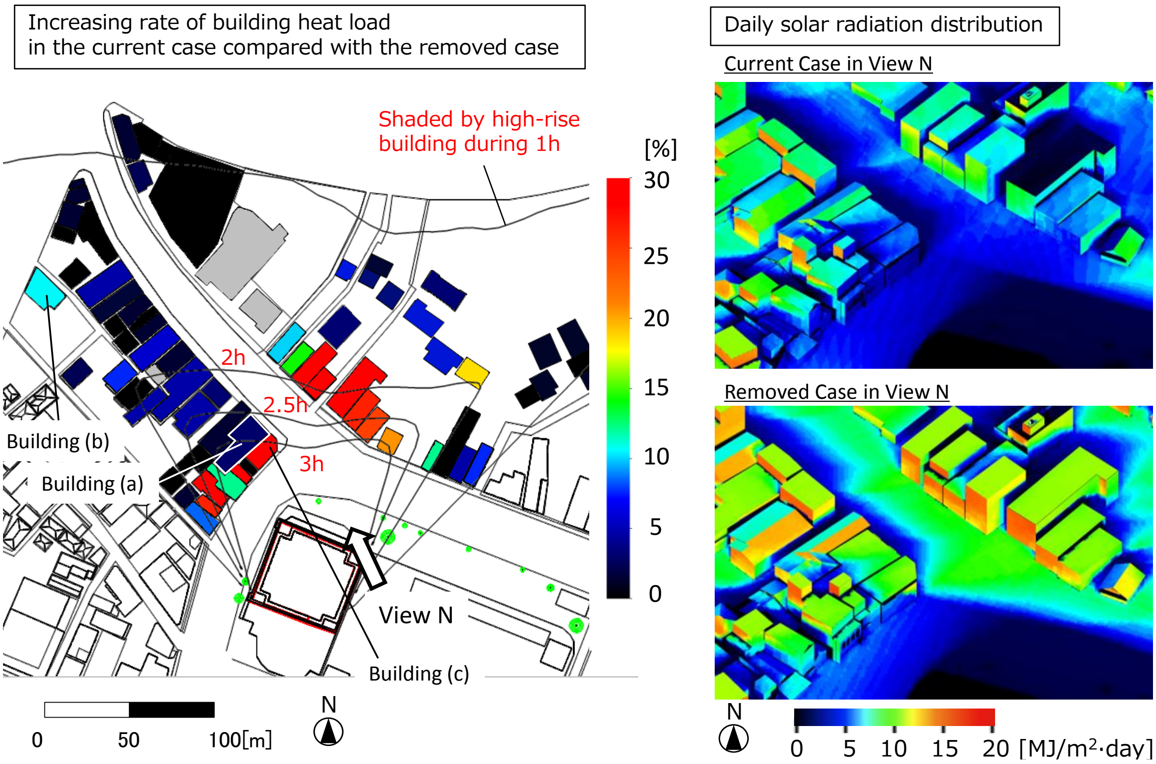

Figure 5 Increasing rate map of building heat load and daily solar radiation distribution in each case

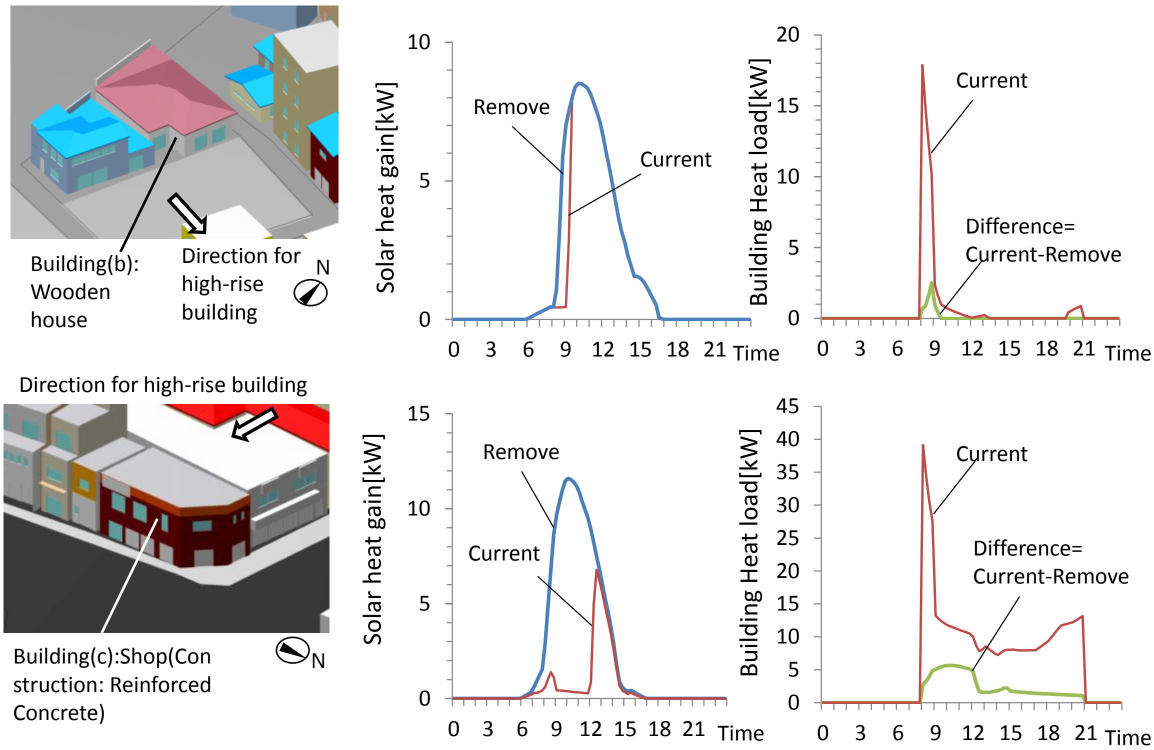

Figure 6 Diurnal change in the solar heat gain and building heat load in buildings (b),(c)

On the other hand, although building (b) is 170 m away from the high-rise building, the rate of increase in the building heat load is 10%. This is because building (b) has windows facing the high-rise building and the adjacent parking lot has no buildings or external objects as shown in Fig. 6.

In addition, different building materials are not affected in the same manner by shading. In reinforced concrete buildings, with large heat capacity, increasing building heat load is observed when shaded by the high-rise building as well as at other times. In building (c), the building heat load is larger than that in the removed case after the building is shaded. The building heat load of buiding (c) in each time from 1 p.m. to 8 p.m. is approximately 30% higher than that at 11 a.m., which is the time when the building is shaded.

CONCLUSION

The shading effect of a high-rise building on the thermal radiation environment in the outdoor space around it and the neighboring buildings heat load in winter is discussed and the following conclusions are reached.

- Shading effect by high-rise building at noon extends widely to the area apporoximately 200m away in the north and the lowest mean radinant temperature in the shaded area decreases 7 °C lower than air temperature. However, in the some space, the shading negative effect on the thermal radiation environment is mitigated by the surrounding space geometry and material. In particular, in the space close to the building wall and ground, which is heated because of solar heat accumulation in the morning, the mean radiant temperature keeps equal to the air temperature.
- In the target district, the northern and western street of high-rise building have many shops with southern or eastern façade with large windows, and these shops are affected more remarkably by high-rise building. The heat loads of these buildings are more than 30% larger than that in the removed case.
- Even for buildings 170 m away from the high-rise building, shading effect on the building heat load is not so little when the building is adjacent to the parking lot and has large window. In this condition, the building heat load increased by 10% compared with the removed case.

The following will be considered for our future work.

- Combine simulation with CFD simulation and study the wind and cold air distribution around the high-rise building.
- Perform simulations of the thermal environment in summer.

Potential for Net Zero Energy Neighbourhoods in the Ahmedabad Urban and Solar Contexts

Janaki Contractor, M.Arch
[Glasgow School of Art]

Filbert Musau, PhD
[Glasgow School of Art]

ABSTRACT

Many net zero buildings have been proposed in different parts of the world. However, there is an argument that an individual building is not the right scale to develop Net Zero Energy Housing. The neighbourhood scale has the potential to integrate not only individual building systems, but also multi-building systems as well as of integrating neighbourhood geometry. This scale also offers opportunities for load sharing between buildings and diversity in functions. Inspite of India having a rich solar energy resource, there are no Net Zero Energy Neighbourhoods being developed. This paper tests the potential of three existing neighbourhoods in Ahmedabad, with different building typology and geometry, to achieve Net Zero Energy status by way of retrofitting Photovoltaic Technology. After a review of historical energy bills to assess the energy demand, the PVSyst software package (version 6.0) is used to test the potential performance of solar retrofits in the three different neighbourhoods. The results show that each of the three neighbourhoods can achieve Net Zero Energy status by retrofitting PV Panels. However, the investment cost and payback periods are prohibitive for the economic contexts of the three neighbourhoods. The paper further proposes neighbourhood scale retrofitting strategies. It also proposes government support policies, based on the neighbourhood scale, to overcome the cost limitations in achieving Net Zero Energy status.

INTRODUCTION

Carlisle, Geet and Pless (2009,4) define a Net-Zero Energy Neighbourhood, as "One that has greatly reduced energy needs though efficiency gains such that the balance of energy for vehicles, thermal, and electrical energy within the community is met by renewable energy". There are mainly two approaches to achieve a Net Zero Energy Neighbourhood. The first one is designing a neighbourhood considering environmental requirements and providing various technologies to balance the energy use and production. Another approach is providing system retrofits in existing neighbourhoods such that the energy produced by renewable sources is equal to the total energy used in the neighbourhood. Retrofit in building terminology usually refers to introducing new technology for a building to be more efficient. Keirstead and Shah (2013, 47) states that since buildings are long-lasting infrastructure, much of the existing building stock will need to be improved if short and medium-term energy efficiency and greenhouse gas reduction targets are to be met. In addition to the benefits achieved by retrofitting individual buildings, area-wide retrofit schemes can offer further benefits in terms of supply-side

Janaki Contractor is a Masters of Architectural Studies student (Urban Design Pathway) at Glasgow School of Art, Glasgow, UK.
Dr. Filbert Musau is a registered Architect and Lecturer in Environmental Design at the Glasgow School of Art, Glasgow, UK.

technologies, optimisation of area wide availability of renewable sources, economics of scale and project finances. However, financing of neighbourhood-scale and individual retrofits of renewables is currently expensive. Today, this technology is not widely applied due to high cost of implementation and long payback periods. Some examples of the neighbourhood approach include Masdar and Bedzed. Masdar in UAE is proposed as a carbon neutral city planned for 40,000 residents. It aims at sustaining 90% energy demand through Photovoltaic energy, while the rest will be sustained by other renewable sources. Although planned to achieve Net Zero Energy, the parts of it that have been executed have succeeded in some aspects but failed in others. Bedzed, designed as Britain's first net Zero Energy Community, also had failures which include its inability to use renewable resources for the combined heat and power plant; occupants behaviour of adding portable heaters resulting in higher than predicted energy consumption. This paper tests the potential of three existing neighbourhoods in Ahmedabad to achieve Net Zero Energy status by retrofitting PV Technology.The neighbourhoods have different housing typology and geometry.

SOLAR POTENTIAL OF AHMEDABAD FOR RETROFITTING PV PANELS

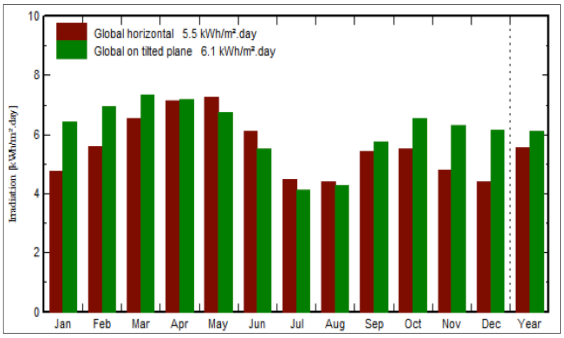

Fig. 1: Solar Irradiation in Ahmedabad based on Pvsyst software simulation. (Source: Authors)

In India, the solar radiation is abundant throughout the year; hence introducing solar photovoltaic technology in existing neighbourhood can reduce non-renewable energy demands. Ahmedabad is situated in the hot semi-arid climate zone of West India and is considered to have summer all year with average temperature of about 27^{o} C to 41^{o} C. It receives high solar radiation (Fig 1) especially in the south direction, hence has high potential for solar energy generation.

For testing the solar potential of the city to achieve a nZEN, a range of Neighbourhoods have been selected according to variation of housing typologies that exist in the city. The first neighbourhood type is the "POL" house – the traditional houses of Ahmedabad, consisting of a number of houses, facing the street and forming a cul-de-sac. Each house is connected to the street by a verandah (semi open space). This study is carried out in "Desai ni pol" situated on the eastern part of Ahmedabad. The second selected neighbourhood type is the apartment, which has grown rapidly in the city due to increased density and land prices. Many different kinds of apartments exist in the city ranging from low cost to luxury apartments with multiple Bedrooms. This study is carried out in Ambawadi apartments located in Western Ahmedabad, in a vicinity of mainly residences with few institution and commercial developments. The neighbourhood has six apartments with a large open space near the entry. Each apartment has three floor levels with four residences on each level. The third selected neighbourhood has the bungalow housing typology, which is spreading fast on the western side of the city due to ample availability of land. Many bungalows exist with large open spaces in the form of gardens with good potential to generate solar energy. However, shading is high in this neighbourhood due to trees. This study is carried out in Rushil bungalows located in western Ahmedabad near SG highway. The neighbourhood has 12 bungalows, each with a garden in the front and a covered backyard.

ENVIRONMENTAL CHARACTERISTICS OF THE SELECTID EXISTING NEIGHBOURHOODS

Pol: Each house has a deep long plot, sharing the longer wall with neighbouring houses, thereby reducing exposure to sun. Dense placements also offer mutual shading to the houses. The courtyard lets the hot air of the house to escape out and allows fresh air to enter. It also provides diffused light to the inner areas of the house. The tripartite windows maintain the inner temperature by allowing the cool breeze to enter and providing shade from direct sunlight. A rainwater-harvesting tank is also located below the central courtyard which helps cool the temperature of the courtyard.

Ambawadi Apartments: These apartments have low energy demand due to their orientation and planning. The periphery of the each floor has balconies, creating an offset for the main living spaces. Generous overhangs protect the houses from direct sunlight, keeping the houses cooler. Moreover each apartment block offers shading to the other block thereby reducing direct exposure of facades.

Rushil Bungalows: These bungalows have very few environmental considerations in their design. They have few openings with overhangs, providing shade from direct sun. However, most openings are not shaded, exposing the façade to direct solar radiation, and therefore heating the house fast in summer.

Fig 2: 3D Massing of the selected neighbourhoods of Pol Houses, Ambawadi apartments and Rushil bungalows respectively (Source: Authors)

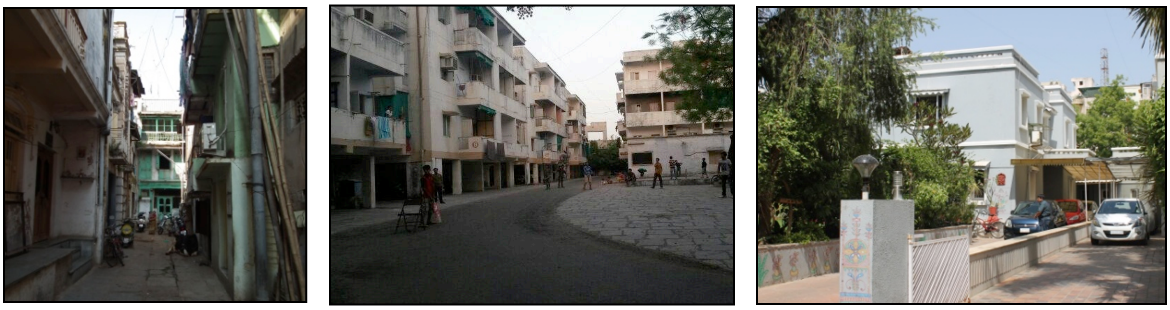

Fig 3:Photos of Pol Houses, Ambawadi apartments and Rushil bungalows respectively (Source: Authors)

For this study, seasonal variation of metered energy bills for selected houses in each neighbourhood was collected and averaged out to arrive at the energy used per household. The energy used per household was multiplied with the number of houses in the neighbourhood to arrive at the total energy used by the neighbourhood. Table 1 compares the energy consumed in each neighbourhood.

Table 1. Comparison of Energy Consumed [Pol (1), Ambawadi apartment (2), Rushil bungalow (3)]

	1	2	3
Energy / House / Month	270 kWh	525 kWh	1550 kWh
Number of Houses	32	72	12
Average number of Persons/House	6	4	4
Energy in Common Uses	-	-	825 kWh
Energy of Neighbourhood / Month	8640 kWh	37800 kWh	19,425 kWh
Energy of Neighbourhood / Year	103,680 kWh	4,53,600 kWh	2,33,100 kWh
Energy consumed per Person	540 kWh	1575 kWh	4856.25 kWh
Floor area / House	60 Sq. m	75 Sq. m	150 Sq. m

Table 1 shows that Neighbourhoods 1 and 2, which are low and middle income housing respectively, have less floor area and hence less energy used per person, when compared to Neighbourhood 3, which is upper middle class housing. Hence it could be concluded that energy used per person is greatly dependent on floor area of units and the lifestyle of residents in each Neighbourhood. From all three selected neighbourhoods, the Pol has the least energy consumed per person.

nZEN POTENTIAL: SOLAR ENERGY PRODUCTION AND COST

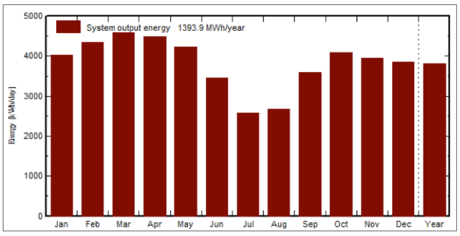

Fig 4 Annual Output of Desai Ni Pol by Pvsyst simulation. (Source: Authors)

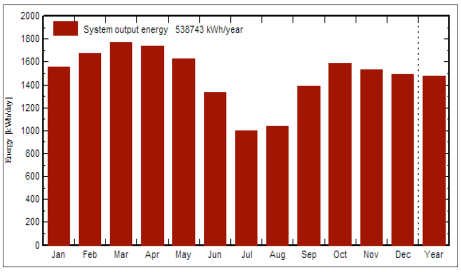

Fig 5 Annual Output of Ambawadi Apts. by Pvsyst simulation. (Source: Authors)

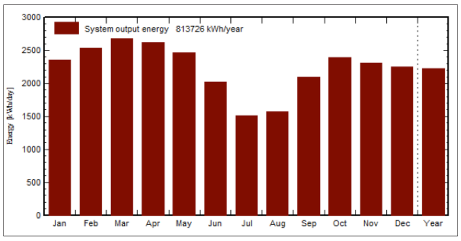

Fig 6. Annual Output of Rushil Bung. by Pvsyst simulation. (Source: Authors)

The shadow studies done in this research suggest that in the Pol house and Ambawadi apartments, the street and the space in between buildings respectively, remains shaded during most of the year, except for noon when the sun is overhead. Similarly in Rushil bungalows the open gardens and main access road remains shaded during most of the day by trees and vegetation.

Hence in all three neighbourhoods, the roof has maximum potential for direct as well as diffused solar radiation. In addition to the roof, the open space in Ambawadi apartments and open gardens and access road in Rushil bungalows have potential for direct and diffused solar radiation respectively. Hence in this study, roof area of all neighbourhoods is considered for solar energy generation.

Table 2 compares the energy produced using monocrystalline panels in each neighbourhood based on available roof area. It suggests that the Energy Produced/Year in Desai Ni Pol and Rushil bungalows, by using entire available roof area, is much more than the requirement of the entire neighbourhood. In Ambawadi apartments, the Energy Produced /Year is almost equal to the requirement of the entire neighbourhood. However, if energy demand increases in future, the neighbourhood can use its open spaces for solar energy production.

Table 2. Comparison of Solar Potential [Pol (1), Ambawadi apartments (2), Rushil bungalows (3)]

	1	2	3
Roof Area Available	4916 Sq. m	1800 Sq. m	2900 Sq. m
Open Space	877.5 Sq. m	3335 Sq. m	4075 Sq. m
Plot Coverage	0.85	0.35	0.41
Energy Demand / Year	103,680 kWh	4,53,600 kWh	2,33,100 kWh
Energy Potential /Year (Generated from PVSyst)	14,75,212 kWh	5,40,151 kWh	8,70,243 kWh
Excess Energy Potential	13,71,532 kWh	86,551 kWh	6,37,143 kWh
Potential Output vs. Demand	14: 1	1.2: 1	3.7: 1
Energy Consumed /Person	540 kWh	1575 kWh	4856 kWh

Table 2 suggests that there is a direct relation between plot coverage and the excess energy produced - the lower the plot coverage (Neighbourhood 2 and 3), the lower the excess energy produced. The more compact the neighbourhood with higher plot coverage and less obstructions, the more the excess energy produced. With proper balance of these factors during the initial design stage, one can achieve nZEN. Table 2 also suggests that the full roof potential to produce solar energy for Desai ni pol, Ambawadi apartments and Rushil bungalows is 14, 1.2 and 3.7 times more than the present demand. Hence, all three neighbourhoods have potential to convert into nZEN as well as produce excess energy.

Similarly, Table 3 compares the investment cost of solar energy production in each neighbourhood. It suggests that in Desai ni pol, Ambawadi apartments and Rushil bungalows the cost that each household would pay annually to achieve nZEN is 2, 1.5 and 1.3 times respectively more compared to the current cost. Also, unit cost of energy increases in all neighbourhoods with retrofitting solar PV.

Table 3. Comparison of Investment and Loan as per Energy Demand of Neighbourhoods [Pol (1), Ambawadi apartments (2), Rushil bungalows (3)]

	1	2	3
Present Yearly Cost/ Household	14,400 INR	31,200 INR	1,26,000 INR
Roof Area according to Energy Demand	346 Sq. m.	1515 Sq. m.	780 Sq. m.
Module Cost	33,95,561 INR	122,44,109 INR	63,03,898 INR
Support Cost	25,96,605 INR	113,69,530 INR	58,53,619 INR
Inverter and Wiring	7,98,956 INR	34,98,317 INR	18,01,114 INR
Transport and Mounting	37,04,577 INR	120,72,796 INR	70,98,285 INR
Total Investment /Neighbourhood	104,95,699 INR	391,84,752 INR	210,56,916 INR
Payback Period	22.7 Yrs.	17.4 Yrs.	13.9 Yrs.
Yearly Cost for Neighbourhood after Loan	10,39,780 INR	37,88,168 INR	20,68,237 INR
Yearly Cost/ Household upto 20 Yrs.	32,493 INR	52,613 INR	1,72,353 INR
Unit Cost	10.01 INR/ kWh	8.33 INR/kWh	8.84 INR/kWh

NET ZERO ENERGY BUILDING (nZEB) VS NET ZERO ENERGY NEIGHBOURHOOD (nZEN); COST AND CHALLENGES

Table 4 compares the nZEN approach versus the nZEB approach with respect to cost limitations and the potential energy generation through solar panel retrofits. It shows that taking a neighbourhood approach is much more advantageous, as it provides availability of more shared renewable resources on site and energy sharing between houses thus helping to achieve Net Zero Energy. It provides more solar access with availability of multiple rooftops and common spaces including open space and streets, when compared to individual buildings, hence providing more unshaded potential area for PV installation. The unit cost of energy is also lower in nZEN approach compared to the nZEB.

Table 4. Comparison of Grid Connected nZEB vs. nZEN: Energy Output vs. Cost [Pol (1), Ambawadi apartments (2), Rushil bungalows (3)]

	1	2	3
Annual Energy Demand / Building	3,240 kWh	75,600 kWh	18,600 kWh
Present Annual Cost / Building	14,400 INR/Yr.	3,74,400 INR/Yr.	1,26,000 INR/Yr
Yearly Investment for nZEB (PVSyst)	50,398 INR/Yr.	7,80,690 INR/Yr.	2,34,137 INR/Yr
Yearly Investment for nZEN/ Building	32,493 INR/Yr.	6,31,361 INR/Yr.	1,72,353 INR/Yr
Unit Cost For nZEB	15.55 INR/kWh	10.33 INR/kWh	12.59 INR/kWh
Unit Cost For nZEN	10.01 INR/kWh	8.33 INR/kWh	8.84 INR/kWh

Table 5: Stand Alone Systems for Individual Buildings Based on Annual Energy Required [Pol (1), Ambawadi Apt (2), Rushil Bungalows (3)]

Infrastructure	1	2	3
Module Cost	1,62,899 INR	3,10,813 INR	7,75,776 INR
Battery Cost	4,73,709 INR	9,04,122 INR	26,43,603 INR
Regulator Cost	82,911 INR	1,30,322 INR	2,77,008 INR
Transport/Fitting	6,21,833 INR	9,77,418 INR	20,77,560 INR
Total Investment	13,41,353 INR	23,22,676 INR	57,73,947 INR
Annuities	1,07,634 INR/Yr	1,86,378 INR/Yr	4,63,316 INR/Yr
Maintenance Cost	1,18,427 INR/Yr	2,26,031 INR/Yr	6,60,901 INR/Yr
Total Yearly Cost/ Household	2,26,061 INR/Yr	4,12,408 INR/Yr	11,24,217 INR/Yr
Unit Cost	69.99 INR/kWh	66.90 INR/kWh	62.27 INR/kWh

Comparing the cost of Stand-alone nZEB (Table 5) with Grid connected Neighbourhood scale retrofits (Table 3); nZEN turns out to be more economically viable. The cost that each household ends up paying annually for a Stand-alone nZEB is about 7-10 times more than that required for an nZEN. This reduced cost in the neighbourhood approach happens because of sharing of infrastructure required for connecting the system to the Grid. The cost of batteries required for storage of excess energy, transport and maintenance is high, as required in Stand-alone systems, acting as a major barrier for nZEB.

Barriers and Challenges

Though connecting to the grid offers incentives of using electricity all year round and selling the excess energy, in India, it faces a few challenges. For an owner, a single point of contact from financing, to operation and maintenance is required for solar PV to be more prominent. However, presence of multiple partners forms a major barrier. Similarly, there might be a problem of ownership in shared rooftops and long-term leasing for solar power generation due to fixed incentives. Moreover, the connection of multiple PV systems to the grid might also have stability issues, hence making it vital to monitor it to avoid its collapse. Also monitoring of energy being fed into the grid to avoid misuses is important. Power generated from other sources if fed into the grid, can lead to a collapse of the feed-in-tariff model. Likewise, availability of different types of devices of diverse quality, for net metering, creates a barrier for precise measure. Hence, establishing a "star rating system" for devices is fundamental for its success.
According to the Technology Strategy Board in UK, neighbourhood retrofits also face challenges due to lack of awareness amongst owners about sustainability and long term gains. The biggest challenge to realise this approach is reaching a mutual agreement amongst families within the neighbourhood regarding investing in this technology. Moreover, lack of competition, choice and availability of materials, higher than expected cost are other challenges making it difficult to implement this technology.

COMPARISON OF USING ALTERNATIVE PANEL TYPES

In order to overcome the cost limitation, since monocrystalline panels are the most expensive PV panel, using different panel types might be a useful option for these neighbourhoods to attain Net Zero Energy. Table 6 suggests that in Pol houses and Rushil bungalow, the amount of energy produced by Polycrystalline and Hybrid Panels is enough to meet demand. However, Table 7 indicates that the cost difference is not sufficient when compared to Monocrystalline panels. The cost of energy per unit also increases by using a less efficient panel. Hence, though using an alternate panel type limits the excess energy produced, the cost of its realisation is more compared to the current cost of the neighbourhood.

Table 6: Comparison of Energy Potential by using Alternative Panel types on entire roof area available [Pol (1), Ambawadi apartments (2), Rushil bungalows (3)]

Panel Type	1:Energy Output	2:Energy Output	3:Energy Output
Energy Demand	1,03,680 kWh	4,53,600 kWh	2,33,100 kWh
Monocrystalline	14,75,212 kWh	5,40,151 kWh	8,70,243 kWh
Polycrystalline	13,83,012 kWh	5,06,392 kWh	8,15,853 kWh
Hybrid	9,22,008 kWh	3,37,594 kWh	5,43,902 kWh

Table 7: Comparison of Unit Cost (INR/kWh) and Yearly Cost (INR/Yr.) using Different Panel Types on entire Roof area Available [Pol (1), Ambawadi apartments (2), Rushil bungalows (3)]

Panel Type	1: INR/ Yr.	1: INR/ kWh	2: INR/Yr.	2: INR/ kWh	3: INR/Yr.	3: INR/ kWh
Present Cost	-	2.8 - 4.3	-	2.8 - 4.3	-	2.8 - 4.3
Monocrystalline	111,94,544	7.59	43,10,750	7.98	66,73,778	7.67
Polycrystalline	107,87,085	7.80	41,44,648	8.18	64,19,822	7.87
Hybrid	87,02,963	9.44	32,92,894	9.75	51,18,930	9.41

SOLUTIONS FOR OVERCOMING COST LIMITATIONS

In order to overcome the cost limitations, an important step would be to reduce energy demand by increasing the efficiency of building envelope. Provision of shading devices for openings and use of better insulating materials in walls and roof would help decrease the overall demand of the three neighbourhoods. In addition, provision of neighbourhood scale retrofits like using efficient streetlights, offering better transportation networks, reducing energy required in pumping ground water, etc. would further help reduce the energy demand of the neighbourhood. After reducing the demand, below are few other ways, which would help overcome the cost limitations of neighbourhood retrofits.

1) Selling the Excess energy to the Government

In each of the three Neighbourhoods, the roof area available has potential to produce excess energy. If the excess energy could be fed into the grid and sold to the government, the payback period and cost could be reduced to a large extent. The State already has a number of privately owned power plants, which sell energy to the state government. According to the Gujarat Electricity Regulatory Commission (GERC) the current rate of buying solar power for all PV Plants commissioned between 1st April 2014 to 31st March 2015 is reduced to 8.03 INR. If each of these neighbourhoods sells their excess energy to the government at the given rate, the yearly instalment would reduce to a large extent. For example in the Pol, yearly instalment on the loan, for the demand energy roof area, would be 32,493 INR. However, after entire roof area installation and selling of excess of energy the neighbourhood has to pay 5660 INR/Yr. (Table 8). Table 8 shows the reduced price that each neighbourhood has to pay after selling excess energy to the government. Hence, in this way major part of the investment amount could be borne by the government, while the residents could pay the remaining amount. However, there are some barriers in this approach – the main one being convincing the government to invest in the neighbourhoods.

Table 8: Selling Excess Energy to the Government [Pol (1), Ambawadi Apts (2), Rushil Bunglows (3)]

	1	2	3
Annual Excess Energy	13,71,532 kWh	86,551 kWh	6,37,143 kWh
Money Received by selling Annual Excess Energy at Rs 8.03/kWh	110,13,401 INR/Yr.	6,95,004 INR/Yr.	51,16,258 INR/Yr.
Yearly Cost / Neighbourhood	111,94,544 INR/Yr.	43,10,750 INR/Yr.	66,73,778 INR/Yr.
Yearly Cost/ Neighbourhood (After selling Excess Energy)	1,81,143 INR/Yr.	36,15,746 INR/Yr.	15,57,520 INR/Yr.
Yearly Cost/ Household (After selling Excess Energy)	5660 INR	50,218 INR	1,29,793 INR
Present Yearly Cost/ Household	14,400 INR	31,200 INR	1,26,000 INR

2) Public Private and Neighbourhood Partnership

Currently few retrofitting strategies have been established in India to promote solar power generation in the domestic context. In Gujarat, the city of Gandhinagar has been promoted as the first solar city, where they aim to produce 5MW of energy through public and private rooftops. The city has tried the Public Private Partnership concept, wherein the private developers would be given access to rooftops of 25 public buildings and around 250 private houses. City dwellers would be given a "green incentive" of INR 3/kWh of energy produced on their privately owned rooftops after Solar PV installations. This serves as a useful strategy of combining private and public investors to invest in solar power generation on local rooftops. However, since this strategy is limited to individual buildings, the roof area available is less giving no neighbourhoods scale energy benefits to house owners. Regarding neighbourhood scale retrofitting strategies, this approach should prioritise installations at the neighbourhood rooftops that are most exposed to solar radiation and should distribute such solar exposure benefits to all dwellings across the neighbourhood. A phased installation approach would potentially help low-income dwellers to distribute capital installation costs for longer periods, thus reducing their monthly repayments.

3) Government Policies, Initiatives and Incentives

Many countries have tried to promote and fund retrofits within the government policies. For example, the UK Government's "Green Deal plan" is a financing mechanism that allows consumers to repay through saving on energy bills for energy saving home installations. Even within India, the Jawaharlal Nehru Nation Solar Mission is an important initiative by the government to promote solar power wherein it targets at producing 20,000 MW of grid connected solar power by 2022. Under the mission, private companies are offered incentives to invest in solar power, by reducing customs duty on solar PV by 5% and exempting excise duty on Solar PV. This is expected to reduce the overall cost of a rooftop solar panel installation by 15–20%. The government also provides Generation based incentives (GBI) and 80% accelerated depreciation income tax benefits on solar energy production. Moreover, the Ministry of New and Renewable Energy (MNRE) in India provides 30% subsidy on the cost of installation of solar PV power plant in all states. However, existing policies target large-scale production of solar power plants and not the domestic sector. Hence, more policies are required, targeting urban neighbourhoods, providing incentives directly to the residents, and helping them achieve Net Zero Energy.

CONCLUSIONS

From the research, it can be concluded that all three neighbourhoods in Ahmedabad have immense potential to produce solar energy and achieve nZEN status. This paper has tested the initial potential of the neighbourhoods and provided rough estimates of investment. The key limitation of this technology is the cost factor and methods have been suggested to overcome this within the solar and economic context of Ahmedabad. With a proper mix of environmental considerations at a design stage- considering orientation, plot coverage and density of a neighbourhood, the energy demand can be restricted. This, followed by government support to implement this technology, by either buying excess power from local neighbourhoods instead of private power plants, or by offering incentives to private and public investors for investing in it at the neighbourhood scale, would help each of these urban neighbourhoods in Ahmedabad to achieve Net Zero Energy. The work suggests that further research is needed to explore links between plot coverage and solar energy in Ahmedabad in order to inform policy on neighbourhood planning to benefit from the conflicting requirements of solar exposure and shading. Further work is also needed on cost reduction strategies to make solar PV more accessible to low income neighbourhoods.

Bioclimatic architecture as an opportunity for developing countries

Barbara Widera, PhD

Wroclaw University of Technology, Faculty of Architecture

barbara.widera@pwr.edu.pl

ABSTRACT

The proper adjustment of the architecture to the climate is one of the basic characteristics of vernacular building. Nowadays this area received an important support through the application of cutting-edge technology. Still, despite the clearly visible change of attitudes towards nature, more detailed analysis often lead to the conclusion that the arising buildings are very rarely based on extensive studies of local bioclimatic conditions. The purpose of this paper is to discuss how the traditional ways of adapting dwellings to the climate are combined with advanced technology and applied in contemporary bioclimatic buildings. Three important case studies are briefly presented in order to demonstrate that the relevant distinguishing feature of bioclimatic architecture is to go beyond the scheme of low-energy buildings, constructed from renewable materials and meeting the conditions of sustainable development certification systems. It is much more vital for the true green design to implement the structures in the ecosystem in such a way that they become an integral part of it. Thus understood bioclimatic architecture is logical, well adapted to the climate and therefore also economical. It creates great opportunities and should be perceived as the solution for the developing countries (as well as for the whole world).

INTRODUCTION

The idea of bioclimatic architecture is closely related to the proper adjustment of the dwelling to the climate. That is also one of the characteristics of vernacular building, based on the traditional ways of adapting architecture to the specific climatic conditions. Vernacular architecture is directly linked to the available resources that influence building techniques (Balbo, 2013, p.37). Furthermore, it is customized to the functional needs and cultural background of the inhabitants. The main difference between vernacular and bioclimatic building lies in the ability to select the technological solution most appropriate to the climate. In traditional architecture that kind of knowledge has been naturally transferred from one generation to another. In bioclimatic building the concept of architecture optimally adapted to the local conditions received an important support through the application of advanced technologies. Due to the combination of traditional climatic solutions and cutting-edge technology, bioclimatic dwelling is well suited to the needs of the contemporary user. The other difference involves proper understanding of complexity and sensitiveness of the natural environment. Bioclimatic architecture is based on holistic approach, including in-depth environmental analysis. Ultimately, the bioclimatic building should become an integral part of the ecosystem and ensure the symbiosis between the cultural and natural processes. However, despite clearly visible change of attitudes towards nature, the alarming datum is that more detailed analysis of projects often lead to the conclusion that although the idea of so-called sustainable design is manifested all over the world, in fact, the arising edifices are

Author is a Ph.D. architect, researcher and academic teacher in Wroclaw University of Technology, Faculty of Architecture, Wroclaw, Poland.

rarely based on extensive studies of bioclimatic conditions as the wider aspect of the problem is sometimes simplified (or even ignored) within the design process oriented towards the energy certification achievement (e.g. Telles, 2012).

Analysis of the various solutions, used in similar climatic conditions, combined with the application of contemporary knowledge allows to develop and to implement technologies that will help to customize the newly erected buildings to the requirements of the modern user. Two biggest challenges in this area are connected with the indoor climate and lighting (McIntyre, 1980; Mahdavi, 1996). Adequate lighting of the interiors with the use of daylight not only positively affects the user comfort, but also has a significant impact on reducing electricity consumption. Although this aspect is considered by the designers more often than the natural cooling, the proper use of daylighting should be further promoted.

The necessary factors of the comfortable indoor microclimate are: thermal comfort, proper air humidity, adequate air exchange rate, the correct oxygen content (this parameter can be improved for example by the introduction of green plants inside the building) etc. In most of developing countries the challenges of thermal comfort derive from the necessity of cooling the indoor air. Despite many criticism, the plant air conditioning systems are so widespread that they are most frequently applied in purpose to provide low temperature and low humidity in the buildings (Mahdavi, 1996). That kind of cooling is commonly used, especially in the offices, retail spaces or public buildings, regardless the high costs, electricity consumption, environmental impact and without considering the application of natural systems, based on local bioclimatic conditions. In many cases the only difference between conventional and so-called sustainable building is limited to the fact a part of electric energy for air conditioning systems comes from photovoltaic panels or other renewable sources.

NATURAL VENTILATION SYSTEMS IN HOT CLIMATE

Cooling systems in vernacular architecture in hot climate zones are based on natural ventilation. Among various schedules observed in traditional dwellings there are three basic models distinguished by Sørensen, that may be applied in contemporary bioclimatic architecture (Sørensen, 2008). These are:

1. Cross ventilation based on the pressure difference across the building shown in **Figure 1a**.
2. Chimney ventilation based on the stack effect i.e. underpressure caused by the rising hot air shown in **Figure 1b**.
3. The wind catchers and wind towers based on overpressure and underpressure presented in **Figure 1c**.

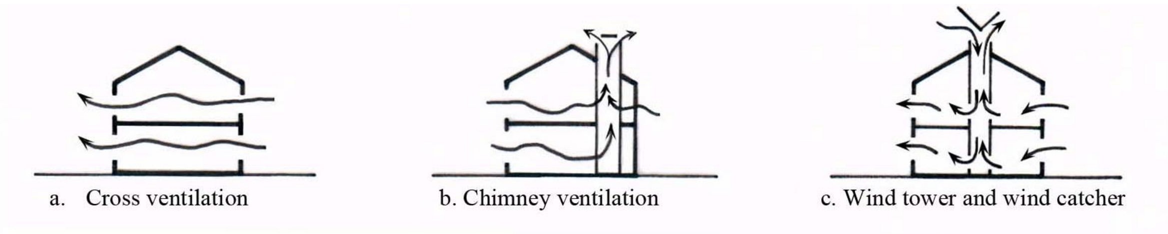

Figure 1 Basic models of natural ventilation. Based on Sørensen (Sørensen, 2008).

In many regions some modifications improve these basic systems. In hot and humid regions, e.g. in Thailand, many traditional houses are openwork and built on high stilts, so that the cross ventilation is combined with the elevated floor as described by Tantasavasdi and presented in **Figure 2** (Tantasavasdi et al., 2001; Tantasavasdi et al., 2007). In Japan, where the temperatures are lower, the floor is slightly raised above the ground. In both cases the air flows under the building to cool it in summer and – in case of the Japanese house – to separate it from the ground in winter. Also in both dwelling types the roof drainage systems (made of natural materials) allow for collecting rainwater.

Different solutions may be observed in hot and dry climatic conditions of Arab countries where the wind towers and wind catchers are quite common. They may be additionally combined with simple but effective evaporative cooling systems described by Hassan Fathy (Fathy 1986) as shown in **Figure 3**. On the basis of these solutions some holistic concepts for bioclimatic architecture were created. The leading architectural workshops in this area are Mario Cucinella Architects (MCA) and TR Hamzah & Yeang.

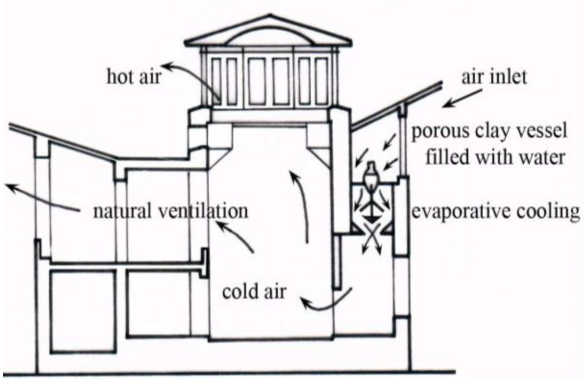

Figure 3 Evaporative air cooling system in Egypt. Based on Fathy (Fathy 1986).

ENVIRONMENTAL STRATEGIES IN THE CENTRE FOR SUSTAINABLE ENERGY TECHNOLOGIES (CSET) DESIGNED BY MCA

Centre for Sustainable Energy Technologies (2006-2008, Ningbo, China) was designed by Mario Cucinella Architects in cooperation with School of the Built Environment, University of Nottingham. The edifice is located in the Nottingham University new campus in Ningbo and it is dedicated to "(…) the diffusion of sustainable technology including solar power, photovoltaic energy, wind power and so forth" (Giorgi, 2006, p.90). The building itself represents advanced environmental strategies developed in direct relation to the local context. A very interesting hybrid system was applied in the project. It is based on the knowledge gleaned from vernacular architecture of hot climate areas (both dry and humid) and successfully combined with high-tech, environmentally safe technology. The non-conventional air-conditioning systems are supported with the cutting-edge technologies for the exploitation of renewable energy sources. The project was created with an intention to take the maximum advantage of the local bioclimatic conditions and to minimize the environmental impact of the building. Following the results of the local climate analysis, the designers developed the structure that allows to reduce the energy demand for heating in winter and cooling in summer. During the intermediate seasons (spring and autumn) the natural ventilation, triggered by a series of automated openings, provides comfortable temperatures and humidity, so there is no need to use plant air conditioning systems. Regarding the climatic conditions it was essential to establish the proper thermal insulation and create massive structures with high thermal capacity. The crucial part of the heating and cooling concept was the carefully controlled air movement within the building.

In hot and humid summer the passive cooling strategies are applied. Thereby the usage of plant systems is significantly diminished and limited only to the hottest days. During the warm part of the year the layer of the ground, located below the land surface, is colder then air. The incoming air is pre-cooled naturally when passing through the earth-to-air heat exchanger constructed in the form of a series of pipes buried in the ground as shown in **Figure 4**. Subsequently the air is further cooled and dehumidified by the air handling unit (AHU). Similarly the ventilation air coming through the air inlet in the tower is cooled and dehumidified by the AHU placed in a coverage. A solar chiller that pre-cools the external air for the tower ventilation is powered by hot water from solar tubes. Thus prepared air is distributed throughout the building. The chimney effect fastens the air exchange and the warm air is removed through the windows placed in the double skin south façade.

High thermal inertia of the green roof in the lower part of the building prevents overheating while thermal mass of the concrete surfaces supports the coolness distribution. The geothermal heat pump produces cold water for cooling the concrete floors. The radiant cooling from the ceilings is effective and healthy so that the mechanical cooling is required exclusively for pre-cooling the incoming ventilation air. In such a way the correct passive cooling design of the building and the high inertia of its concrete structure provide optimal indoor microclimate during summer.

The angles and materials of the southern part of the building were designed to pre-heat ventilation air in winter. The external air inlets are located on the ground level, at the bottom of the double skin façade so that during sunny days the air is naturally heated by the passive solar gains. After reaching the appropriate temperature the air is distributed in the edifice. Other air inlets are situated in the ground, outside the building. The incoming air is pre-heated by the earth-to-air heat exchanger. Further heating is provided by the geothermal heat pump, which is powered by energy from the photovoltaic panels. The air heating system is integrated with the radiant air-conditioning ceiling. The radiating coils embedded in the floors are activated when it is necessary to heat ventilation air. The heat is stored by the concrete ceiling slabs and released gradually to provide proper thermal comfort during the day. The northern façade is well insulated to avoid heat loss during the cold season of the year. The heat transfer coefficient of the opaque walls is 0,25 W/m²K and of transparent parts 1,2 W/m²K.

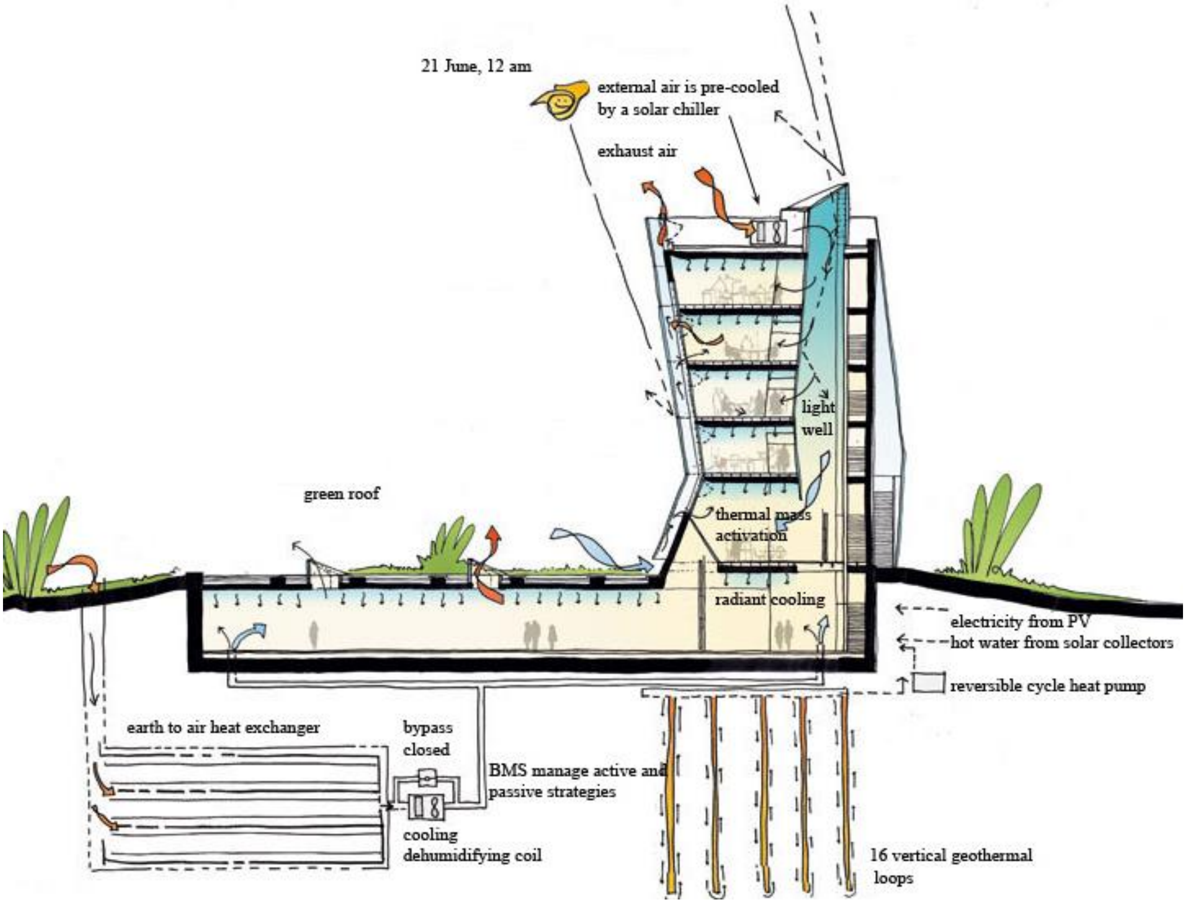

Figure 3 Centre for Sustainable Energy Technologies (CSET, 2006-2008, Ningbo, China) by MCA, environmental strategies – summer. Drawing © MCA.

The whole building envelope was designed in favor to provide maximum usage of natural light as it was possible without glare and overheating during summer. Such solution reduces the use of artificial lighting and thus also the electric energy consumption. All the necessary artificial lighting systems are characterized by high luminous efficiency and low power consumption. Electricity, required to power that lighting as well as the office equipment, comes from especially redesigned photovoltaic system. The energy surplus produced during maximum solar radiation periods can be stored in batteries or sold to the nearby sports center. The BEMS (Building Energy Management System) controls the building operation and manages active and passive systems to optimize comfort level, while reducing energy consumption.

All the environmental strategies were chosen in purpose to create contemporary bioclimatic building that provides proper balance between local climate factors (sun angle, air and earth temperature in different seasons, wind, humidity), ecosystem (plants and species of the area), technology (including renewable energy sources) and the occupant needs (indoor comfort, reference to Chinese culture). The educational value of the project is connected with promotion of the concept of bioclimatic architecture that derives from the environmental studies and therefore is very well adapted to the natural and cultural context.

BIOCLIMATIC ARCHITECTURE AND ECOSYSTEMS

It should be noted that while sustainable development program in architecture strongly accentuates local aspects, under the label of sustainable architecture there is often an attempt to create a global golden rule of architecture. The evaluation methods are inherently characterized by some averaging, but the creation of the built environment truly adapted to the bioclimatic conditions requires an individual approach. Conducting environmental analysis is necessary each time for the specific location. Moreover, due to dynamic nature of ecosystems, analyses should be repeated and changes monitored (Yeang, 1996). Increased attention is given to the relationship between the architecture and the ecosystem (Hart, 2011). Ken Yeang, one of the most important creators and promoters of bioclimatic architecture, notes the necessity of integration of the following Eco Infrastructures:

1. Green **-** connected with natural habitats and the environmental biodiversity.
2. Gray **-** related to engineering that include sustainable energy and technologies oriented towards low environmental impact as well as zero CO_2 emissions.
3. Blue **-** concerning water management, rainwater harvesting and gray water recycling.
4. Red **-** referring to human culture i.e. law regulations, social norms and habits, user comfort, standard expectancy, materials as well as the human impact on the environment.

Each part of infrastructures described above is analyzed and developed in close relation to the existing ecosystem, with the intention to restore, preserve and enrich its equilibrium and biodiversity. Proper implementation of that strategy into the bioclimatic design leads to the authentic adaptation of architecture to the local context. Thus created holistic approach is an important distinguishing feature of bioclimatic architecture.

RELATION TO THE ECOSYSTEM ON THE EXAMPLE OF SOLARIS BUILDING DESIGNED BY TR HAMZAH & YEANG

Holistic and consequent approach to bioclimatic architecture can be observed in Solaris (2011, Singapore,) designed by TR Hamzah & Yeang. This 79-meters high structure is situated in Fusionopolis, in the area of the former military base which now became a fast developing business and research area of Singapore. Since the existing ecosystem was seriously damaged, one of the main goals of the architects was to restore and enrich its biodiversity in purpose to create equilibrium of the natural and built environment. Therefore the continuous perimeter ramp, with a length of 1500 meters, was designed to introduce maximum amount of green area into the building. The landscaped ramp established the link between One-north Park that reaches directly the building façade and Solaris towers. The higher tower has 15 and the lower 9 floors. Both of them house research facilities and offices. All the areas of the building are connected to the spiral ramp and passively ventilated atrium. The service path that goes through the ramp provides direct access for plants maintenance and is used as the linear park that leads up to the roof gardens on the top of each tower. This continuous landscaped spiral with a minimum width of 3 meters was designed for the benefit of the environment, as it enables fluid movement of small organisms between green areas of the edifice and thus contributes to biodiversity and health of the ecosystem. At the building corners the ramp expands to the terraces. As a consequence total landscaped area of the project covers 8,363 m^2, with the site area 7,734 m^2. That results with 108% ratio of landscape to site area and 95% of the landscaped area located above the ground level.

Bioclimatic concept combines traditional solutions developed for hot and humid climate zones with the most contemporary technology and knowledge. The climate-responsive façade design is based on studies of local climatic conditions, including the sun-path analysis. The specific building location at the equator and the east-west sun-path affected specific requirements of the façade shading. The first element of this strategy is the ramp with deep overhangs and the abundance of shade plants. The second solution in favor of the ambient cooling are the sunshade louvers with shape and depth determined directly by the solar-path analysis. The louvers and the green ramp created a pleasant buffer space which significantly reduced solar gains and glares. Consequently the heat transfer through the low-e double-glazed façades was also considerably decreased. The external thermal transfer value (ETTV) of the whole system is 39 W/m^2.

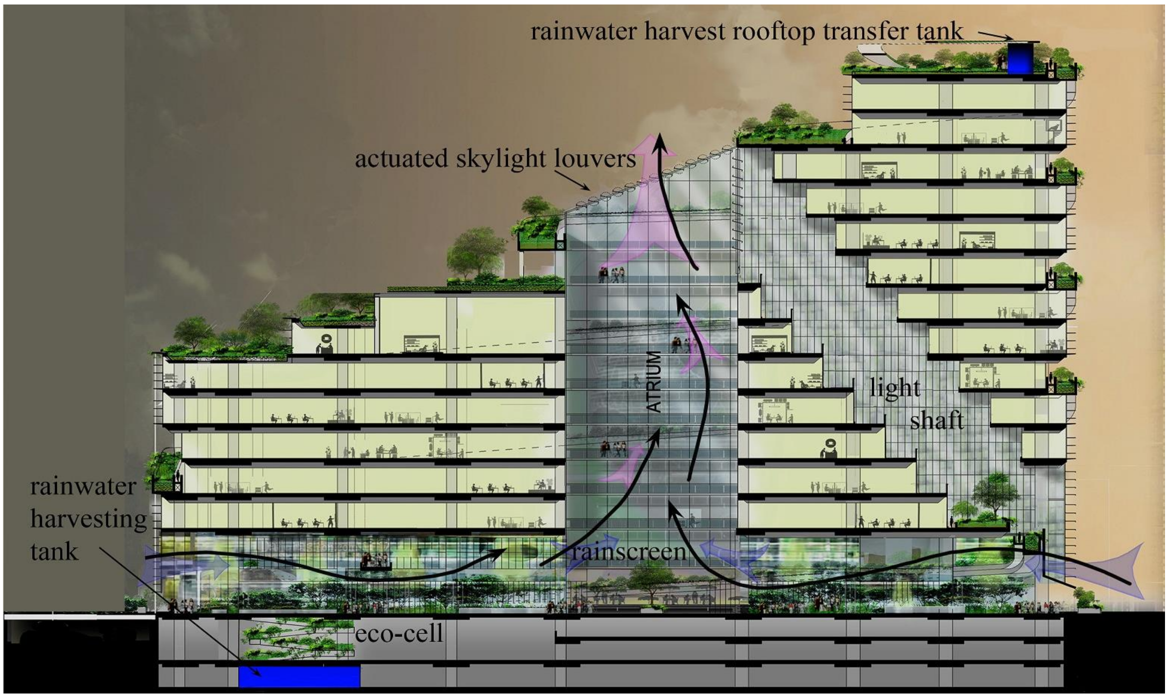

Figure 4 Solaris (2011, Singapore), by TR Hamzah & Yeang, bioclimatic section. © TR Hamzah & Yeang.

An atrium situated between the two towers is fully passively cooled and supports natural ventilation and daylight distribution within the internal areas of the building. An operable glass-louvered skylight system was installed on the roof over the atrium to enable stack effect cooling. Computational Fluid Dynamics (CFD) simulations were carried out to provide optimal thermal comfort with the controlled air flow in the atrium. Simultaneously, the active energy use was diminished. Both the louvers and the rainscreen walls are controlled by climate-responsive sensors to ensure protection against the precipitation and to allow natural ventilation during the rain. The atrium is directly connected to the landscaped area on the ground floor, linked to One-north Park which allows for cross ventilation. In order to provide optimal daylight penetration within the building's interior, the diagonal solar shaft was designed. It crosses the structure from the top of the higher tower down to the street level. The solar shaft gained more attractiveness with the landscaped terraces situated inside. Additional daylight is received from the façade shading louvers that create also double light-shelves and redirect the light into the building. To optimize the system performance a series of sensors measure the illumination level. When the sensors register a sufficient amount of daylight, the artificial lighting is automatically switched off. Thereby the energy consumption is reduced. As pointed out by Council on Tall Buildings and Urban Habitat (CTBUH), the reduction in overall energy consumption in Solaris building reached 36% compared to relevant precedents (CTBUH, 2012).

Due to the large amounts of vegetation located within the building, it was necessary to solve the problem of irrigation in an efficient and environmentally safe way. Based on the concept of bioclimatic design the attention was focused on the high average of rainfall in the area. Consequently a large-scale rainwater recycling system was proposed. Rainwater is harvested on the roof via symphonic drainage and on the perimeter ramp with the drainage downpipes. It is then stored in rooftop tanks and at the lowest basement level, beneath the place called Eco-cell. Eco-cell is located on the ground level at the building's north-east corner, at the beginning of the ramp. It allows for penetration of natural light and ventilation air as well as for the plants extension into the car-park area below. A total storage capacity of Solaris rainwater tanks is over 700 m^3, which almost entirely covers the demand for watering plants. An integrated fertigation system provides plants with essential organic nutrients.

The project of Solaris building is adapted to local context on many levels. Similarly to CSET the design concept is based on analysis of the environmental factors, such as sun-path, sun angle, temperature and humidity. Moreover, the project’s bioclimatic strategy seriously takes into account the individual character of the ecosystem, including the need to restore and enrich its biodiversity. Consequently, the idea of bioclimatic architecture is created in equilibrium with the natural environment.

Two edifices described above: CSET and Solaris, are pioneering on a global scale. Promotion of such an approach is extremely important, as it helps to establish a model for developing countries. However, it is worth to notice that on a local scale it is possible to create bioclimatic architecture also with much lower budget. Solutions based on contemporary knowledge and technology, well inscribed into the local conditions and determinants, can be implemented at minimal cost. An impressive example was set by MCA who designed the school in Khan Younis, in the Gaza Strip.

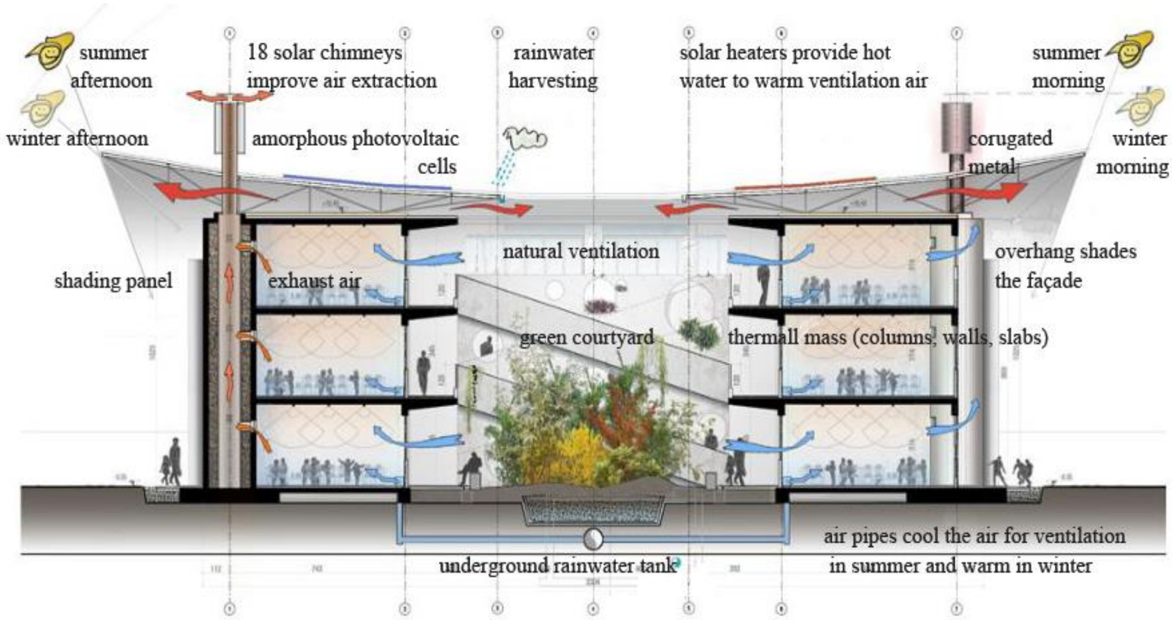

Figure 5 Kuwait School in Khan Younis (Gaza Strip, from 2014) by MCA. © MCA.

KUWAIT SCHOOL IN KHAN YOUNIS, GAZA STRIP, BY MCA.

The project of Kuwait School in Khan Younis (Gaza Strip, from 2014) was developed by MCA in partnership with UNRWA (The United Nations Relief and Work for Palestine Refugees in the Near East), with the financial support of the Kuwait Fund for Arab Economic Development. The aim of the concept was to create a green school that will provide high user comfort for 1500 children and will be totally safe for the natural environment. As the project is dedicated to the challenged area of Gaza Strip, where an access to most of resources is very limited, all the materials have to be affordable and locally sourced. The lack of fresh water is a very serious problem in Gaza Strip. Electricity is produced from generators that cause environmental pollution. To deal with this facts Cucinella proposed the pilot project to promote green approach, which may be "part of the solution to the demographic boom in Gaza where people are struggling to build homes and schools with the resources they have" (Aburawa, 2012). Therefore an off-grid building, possible to build only with locally available and renewable resources was designed. All the construction systems are as simple as possible, avoiding excessive use of advanced and expensive technologies. The only exception concerns the implementation of photovoltaic cells, solar panels and thermal technologies that improve the quality of life without harming the environment.

The Kuwait School was designed as bioclimatic building, well adapted to the local climate and environment, with an intention to enhance the biodiversity of the ecosystem. The whole construction was created in such a way that its elements support bioclimatic strategies. The concrete foundation slab provides thermal mass. Low-cost pillars designed to increase inertia, are made of concrete-earth blocks pre-casted on site, with a diameter of 2,2 m and the inner cavity filled with ground from the excavation. Vaulted slabs are made of compressed earth block. Thus formed flat arches represent traditional and very simple building technique which does not require any formwork. Overhanging roof is made of inexpensive steel beams and reflective corrugated metal sheets. The overhang allows for natural ventilation and shades the earth-brick walls. Thermal control in the building is achieved with the earthen walls and floors providing thermal mass and protecting the interiors against direct solar gain during hot days as well as against cold winds. Further elements that prevent overheating are the façade shading panels and the overhanging roof. Air pipes, located beneath the foundation slabs, cool the ventilation air in summer and heat it in winter. 18 solar chimneys fasten the exhaust air extraction from the building. Finally, the inner courtyard was designed to create pleasant green area, support natural ventilation and reduce heat island effect.

Electricity, necessary to power electrical devices, will be provided by l272 m^2 of amorphous photovoltaic cells located on the roof. Hot water for the heating coil will be delivered from 100 m^2 of the vacuum solar heaters. The classrooms will be naturally illuminated with daylight. Such designed building will have zero CO_2 emissions, will use zero oil and its heating demands will be 7 $kWht/m^2$ per year with 0 $kWht/m^2$ per year for cooling purposes.

The rainwater harvested from the roof will be used for the hygienic purposes. It will be stored in an underground tank. The recycled waste water will be used for flushing toilets (grey water) and for the plant irrigation (black water). This strategy will result in reducing water demand by 60 %. Each year water savings will bring 4600 m^3/y from waste water and 486 m^3/y from rain water.

In the project there are numerous references to the local tradition that makes it more accessible to residents and allows to express respect for their cultural heritage.

CONCLUSION

In the three case studies presented above traditional solutions developed in vernacular architecture were used as the inceptive idea as well as the source of inspiration for contemporary bioclimatic buildings. Basic methods of passive cooling and natural ventilation, commonly used in hot climate areas, were hybridized to achieve the optimal performance. In purpose to obtain the high level of indoor microclimate comfort, corresponding to modern user expectancies, advanced technology was applied. In first two edifices their budget allowed for some exemplary technological solutions, especially regarding climate responsive façade design as well as air preparation and distribution throughout the building. In CSET the non-conventional air-conditioning systems were supported with cutting-edge technologies for the exploitation of renewable energy sources. In Solaris the issue of restored, enriched biodiversity and the equilibrium of natural and built environment was of the utmost importance. The project of Kuwait School proved that the contemporary knowledge and technology, well inscribed into the local conditions and determinants, can be implemented at minimal cost. While photovoltaic cells, solar panels and thermal technologies were used to improve the quality of life, the whole architectural conception is based on passive strategies, simple construction methods and locally available, renewable resources.

The study presents the concept of bioclimatic architecture through the proper balance between traditional ideas and modern technologies. This notion allows for practical and creative usage of contemporary knowledge transfer. Nowadays original methods, dedicated to various climatic determinants, developed and verified in different parts of the world, can be supported and improved by the application of cutting-edge technologies. Although in-depth analysis of local biological and climatic conditions should always be a starting point, the worldwide information exchange can result in entirely new hybrid systems designed for the specific location needs. It is worth to note that such an approach may be used also in the areas where the lack of indigenous examples hinders the selection of the most appropriate bioclimatic solution solely on the basis of vernacular buildings studies. Therefore the contemporary bioclimatic architecture can be defined as one that combines traditional knowledge about ways of adapting dwellings to the climate with advanced research, design and technological methods in purpose to create the built environment maximally integrated with the natural environment and especially with the ecosystem in which it is placed.

It should be emphasized that buildings that are well adapted to bioclimatic conditions do not exceed the budget for comparable facilities while their environmental impact is minimal. Growing respect for ecosystems results with architectural projects that enhance biodiversity for the benefit of natural and cultural environment. Thus understood bioclimatic architecture creates great opportunities and should be perceived as the solution for developing countries (as well as for the whole world).

ACKNOWLEDGMENTS

The author wishes to express her thanks to the Authors of presented projects and especially Professor Mario Cucinella and Professor Ken Yeang who supported her not only with all the necessary materials but also with valuable comments and incredible kindness.

ABSTRACT

This paper will explore how we can move from whole building energy usage data to that which can now include component level energy data (i.e., envelope assemblies). This paper will discuss a recent installation in a new campus building of a distributed low cost data acquisition system that can monitor at the component level. Five different wall/roof orientations were selected to have thermocouple sensors placed through the building envelope assembly. All these sensors will be connected to a programmable logic controller which will be integrated with a campus wide website. This system will not only become the new campus standard but will also have an enormous educational benefit to students who use this website.

INTRODUCTION

In 2010 it was estimated the value of all U.S. commercial real estate was $11.5 trillion,[1] yet the industry knows very little as to how well their buildings are performing from an energy standpoint. ASU has taken a leadership role in understanding whole building energy usage in its campus buildings by developing a campus-wide Energy Information System (EIS) and placing portions of that data on an open website called Campus Metabolism.[2] This work has received considerable acknowledgement from both the energy management as well as from the academic communities. The next step in providing leadership in this area is to provide the industry a component level energy monitoring system to understand how individual building assemblies operate in real-time.

PROJECT BACKGROUND

The origins of this project started with Campus Metabolism which is an ASU public website that displays real-time energy information for select buildings on ASU's Tempe campus. Campus Metabolism offers a unique inside view into the university's commitment to sustainability initiatives, including its focus on the value of energy efficiency and using alternative energy resources.Campus Metabolism was first commissioned in 2004, in partnership with Ameresco (formerly known in Arizona as Arizona Public Service Energy Services), after the university installed utility-grade instrumentation to accurately monitor energy usage of its buildings on campus. This data was first used by ASU's Energy Information System (EIS) from which it can be passed to other applications.

Building on the performance data being generated by the Energy Information System, Campus Metabolism extends this capability by bringing a wealth of valuable energy information and presenting it graphically for use by students, researchers and the general public. Campus Metabolism is very user-driven by allowing the user to select and graphically present energy performance data in a number of innovative ways. This site allows the user to view either the heating, cooling, electricity or the total energy consumption of the building on a daily, weekly, monthly or yearly basis. These displays also present energy data from the previous time period (day, week, month or year), thus allowing for easy historical comparisons. Figure 1 illustrates a typical screen from the Campus Metabolism website – showing kWh electricity usage in yellow and the previous days kWh electricity usage in grey.

Campus Metabolism has proven to be a very exciting tool with a high level of usage; unfortunately data that is generated is at a macro level. The macro level of monitoring a building's energy use has come a long way in the last few years; however, it

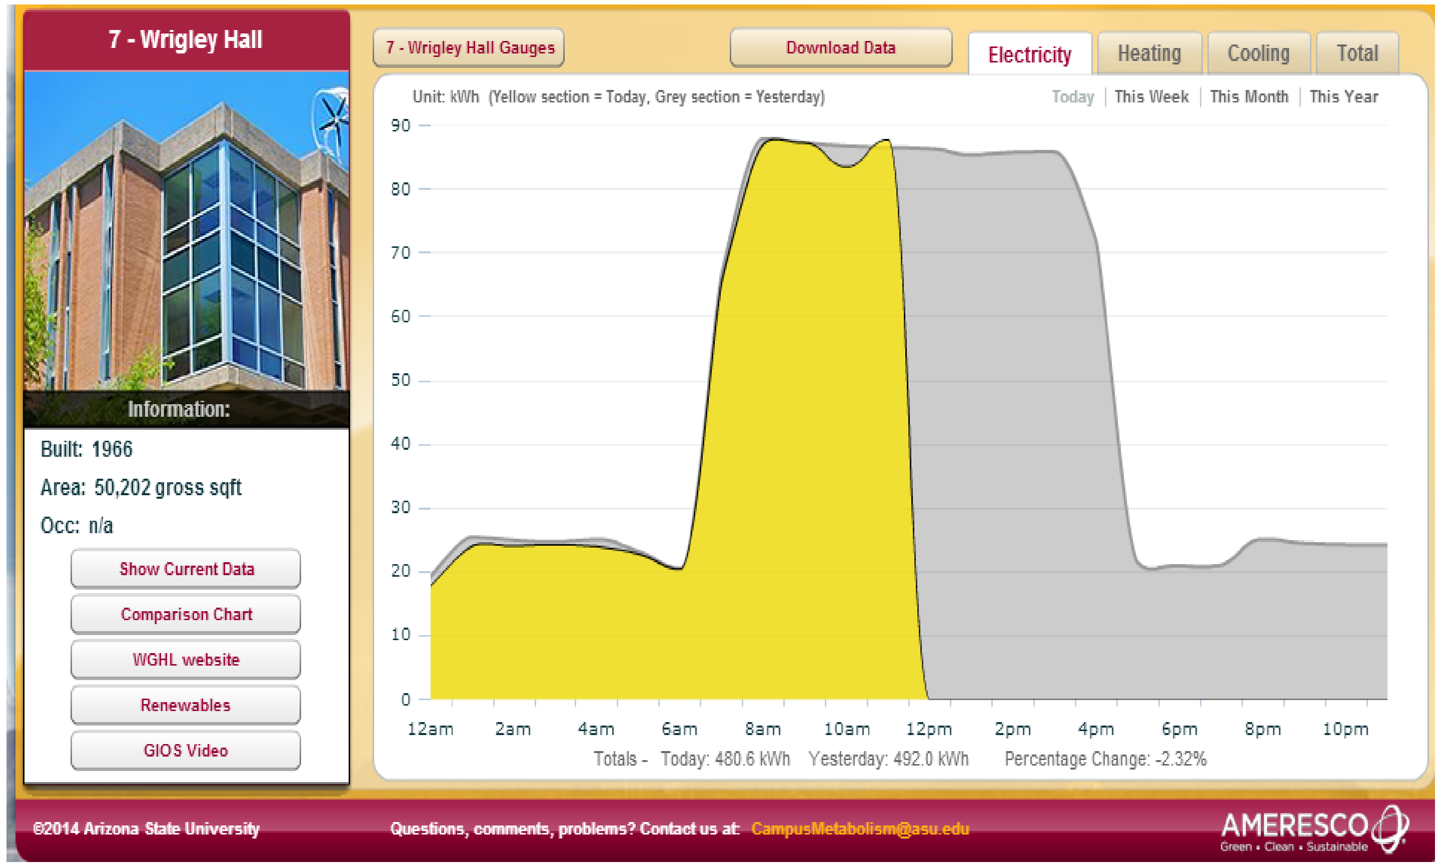

Figure 1 Typical Campus Metabolism Screen Image – Showing Daily Electricity Usage for Wrigley Hall.

is often not disaggregated enough to generate data that will identify how areas that might have small energy loss that can add up to have major energy impacts. We believe we now have the potential to install in a new campus building a low cost distributed acquisition system that can monitor down to the micro (component) level. We hope that this system will become the new standard for ASU and allow ASU to once again provide much needed leadership in the area (like it did with the release of Campus Metabolism).

Having the ability to have this type of instantaneous real-time monitoring of a building's components, such as walls and roof will have many benefits. For example, procedures for determining the thermal resistance (R-value) of building assemblies have for the most part been a theoretical exercise. R-value testing is usually done in laboratories where the testing is not started until the material reaches "steady state." Steady state occurs when a material is exposed to a heat source and is allowed to become thermally saturated so that for every single unit of heat entering on one side of the material a single unit of heat exits the opposite side. While very scientific and logical it misses an important issue relevant to predicting in-situ performance – which is the amount of time it takes to reach a steady state. Heat-balance modeling can takes this dynamic into consideration; however, for in-situ conditions it has been very difficult to determine given changing temperature and varying solar heat gain during a typical day. Thus, being able to have the ability to take a "snapshot" at any given time of day and then capture the solar gain, ambient temperature, and all surface temperatures at each layer of wall or roof construction we are confident that a more accurate R-value can be determined for each layer of wall or roof assemblies. Such information will also provide an enormous benefit to researchers, building design professionals as well as students and any parties who are interested in understanding how individual building assemblies perform in real-time.

Author A is a professor in The Design School, Arizona State University, Tempe, Arizona. Author B is a graduate student in The Design School, Arizona State University, Tempe, Arizona.

PROJECT DESIGN

Five different wall/roof orientations within ASU's new College Avenue Commons (CAC) were selected for monitoring. The CAC is a 137,000 square foot, five-story building for ASU's new School of Sustainable Engineering and the Built Environment. Each orientation would have the exterior wall/roof monitored by sensors placed in a linear fashion through the envelope assembly, starting on the outside. At each subsequent material layer there will be a thermocouple measuring temperature. The final interior sensors will be heat flux sensors located on the inside surface. All of these sensors will be connected to a standard programmable logic controller (PLC) which will be integrated with other campus wide monitoring systems, as well as connected to the Internet. From there users can access this data via their personal electronic devices (tablet, smart phones or computers).

In addition, to understand the external microclimatic variations, a local weather station will be installed on the roof of the CAC. This station will not only measure the standard weather parameters (like dry bulb, wet bulb, wind speed and direction) but will also include four pyranometers (solar radiation sensors) that will be oriented to measure the exact amount of radiation that each of the building's four orientations are receiving. This is vital data for determining the correct amount of solar radiation and its direct impact on performance of each of the envelope assemblies' orientations.

Figure 2 illustrates a wall section and mock-up of how the thermocouples were placed in a typical wall. The first sensor was placed on the outside of the metal cladding, the second in the air cavity of the metal cladding, the third on the outside surface of the insulation board, the forth between the insulation board and the closed cell spray-in insulation, the fifth on the inner surface of the closed cell spray-in insulation, the sixth on the cavity side of the gypsum board and the final sensor (which is a heat flux sensor) was placed on the room side of the gypsum board. The blue strip shown on the wall section drawing between the closed cell spray-in insulation and the gypsum board is the location of the humidity sensor.

The installation of the envelope sensors took place over several months. This was because we decided to wait for each trade to be finished with their work. Thus, we incrementally added sensors as each material layer of wall or roof was completed. While this added time it allowed for more accurate placement of sensors at the boundary of each material layer versus drilling holes after the wall or roof assemblies were completed. Informing each trade about the nature of this project was important so that sensors and wires would not get disturbed or inadvertently cut. As a whole, the CAC contractors as well as each trade were very supportive and interested in its potential outcome of this project.

The classroom spaces that are directly adjacent to each of the envelope monitors will have a large LCD display that will allow students in those spaces to monitor real-time envelope performance. One of these spaces is designated to be ASU's new HVAC Laboratory, which will be a teaching/research laboratory fitted with dual operating HVAC systems (a Variable Air Volume system and a Chilled Beam with a Dedicated Outdoor Air System) that can be switched between their operations. Here we would expect the classroom instructors to develop a host of learning exercises that would utilize the envelope performance data being generated to explore and test innovative HVAC operations. Thus, with the coupling of envelope monitoring with the HVAC Laboratory, a host of very innovative whole system research questions can also be asked and answered. While not the subject of this paper, we expect that a series of future technical papers will emerge from having such an innovative HVAC Laboratory operating in one of our campus buildings.

RESULTS

As of the time this paper was written, the CAC building is occupied, unfortunately the envelope sensors and data recording capability are only now being commissioned. Thus, rather than showing full operation of the five wall/roof sensor arrays we will show the three proposed Campus Metabolism screen templates that will house the sensor data and allow for display. We will also show measured data from the first wall sensor array that has been commissioned. We expect that at the time of the actual PLEA 2014 Conference (December 2014) to be able to show the real-time functional screen images of the envelope sensor pereformance from the new Campus Metabolism website.

Figure 3 illustrates the Campus Metabolism screen that would appear after a user selects the College Avenue Commons building. This screen has a brief description of the building along with four areas (Chilled Beam, Lighting, Wall Sensors and Roof) for which real-time data is available. By selecting one of these areas, a more detailed screen will appear. In our case we will select Wall Sensors which will open Figure 4. This screen shows an image of the CAC building on the left with the wall

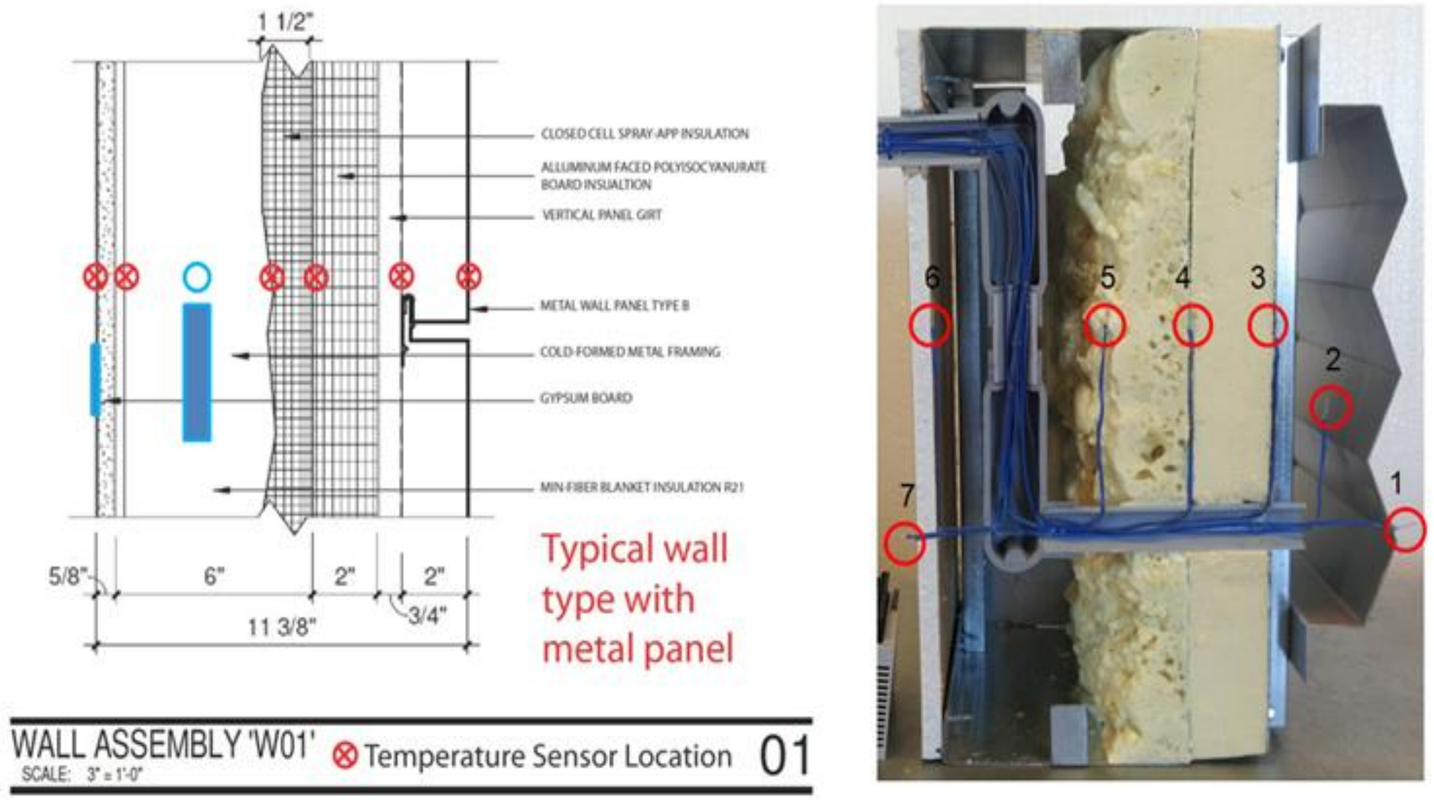

Figure 2 Typical Wall Section and Mock-Up of Thermocouple Placement (Circled in Red)

sensor placement highlighted with red dots, and the three rooms located adjacent to the sensor placement appear on the right side. By selecting the "View Snapshot" button, Figure 5 will open. In this screen we will select Room 425, which again shows an image of the CAC building on the left and below is a description of Room 425. Also on the left below the room description is a floor plan highlighting Room 425 in red and the sensor placement with a red dot. On the right side of this screen is a temperature profile through the wall section showing the temperature at each material layer. Below the temperature profile are four options (Last Hour, Last 24 Hours, Yesterday and Custom) which illustrate temperature profiles for those conditions. The Last 24 Hour option is an animation of hourly temperature changes over a 24 hour period. The Custom option allows the user to set-up a temperature profile for any time frame they would like. Finally "Current Conditions" are recorded below the temperature profile, which include data generated from the building's weather station.

Figure 6 is plot of a 24-hour temperature profile for each of the eight sensors that were embedded in the south wall of Room 425. This data was gathered on June 30, 2014, while the overall data acquisition system was being commissioned. Thus, it is very preliminary data and we are a little hesitant to interpret too much from this data. We would much rather wait until all the wall, roof and weather station data has been synchronized and operating in real-time. For example, it is not obvious why the outer sensors (in and around the metal cladding) are so spiky at the mid-day hours without the ability to review the pyranometer data for that same time period. We hope to be able to present much more in the way of interpreted findings at the time of the actual PLEA 2014 Conference. In the completed Campus Metabolism website, Figure 6 would become the 24-hour snapshot screen on the right side of Figure 4.

CONCLUSION

This project has taken what is usually done in a laboratory and turned the building into the laboratory that can monitor in real-time to show and graphically represent the actual thermal performance of each layer of a typical envelope assembly. This exercise outlines an effective approach for determining real-time temperature performance of envelope assemblies. It is of growing importance to understand how buildings perform down to the component level. Information like this will lead to better

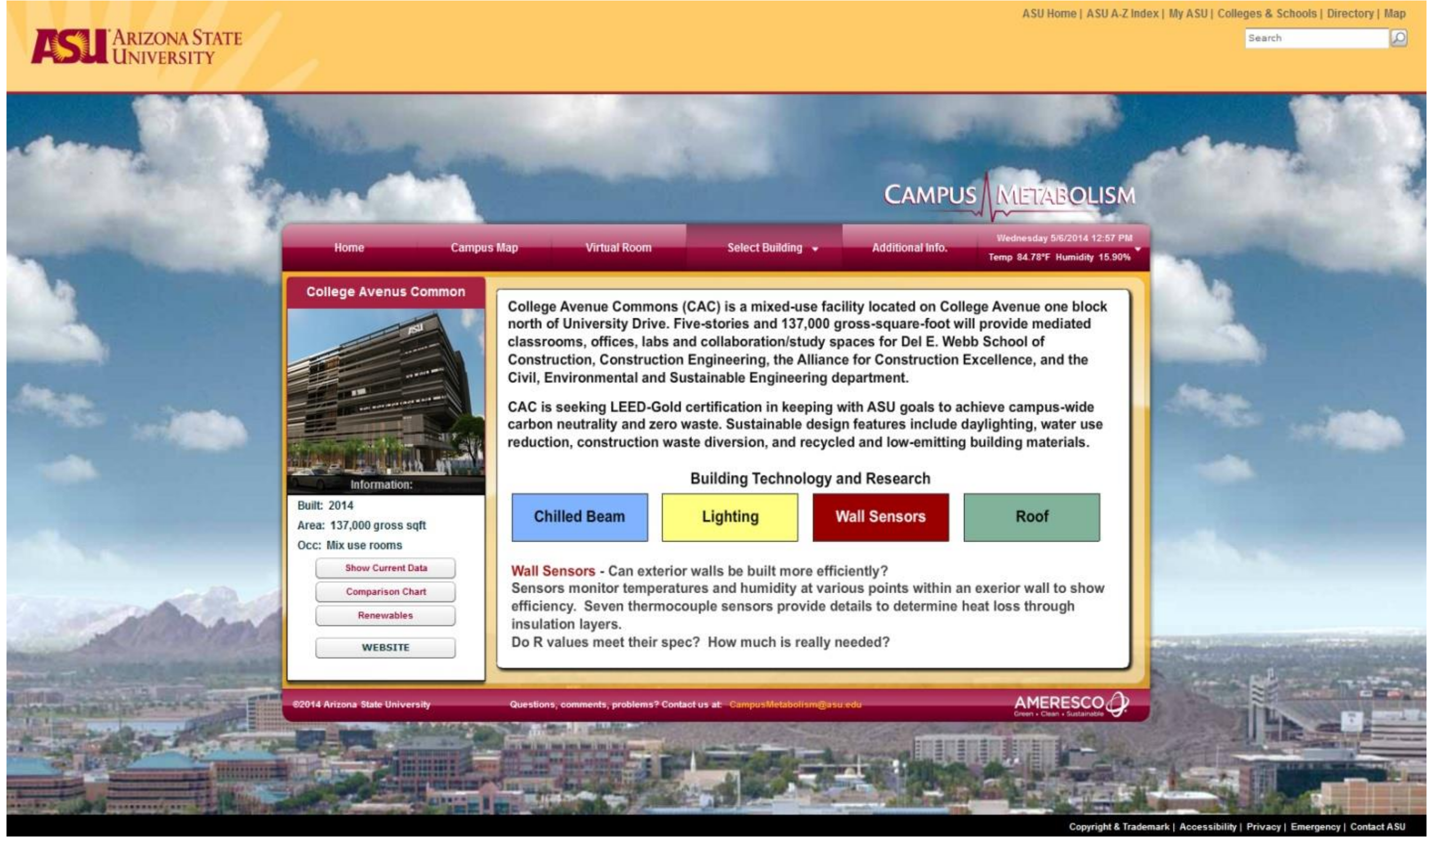

Figure 3 Screen describing the CAC and showing the four areas for which real-time data is available.

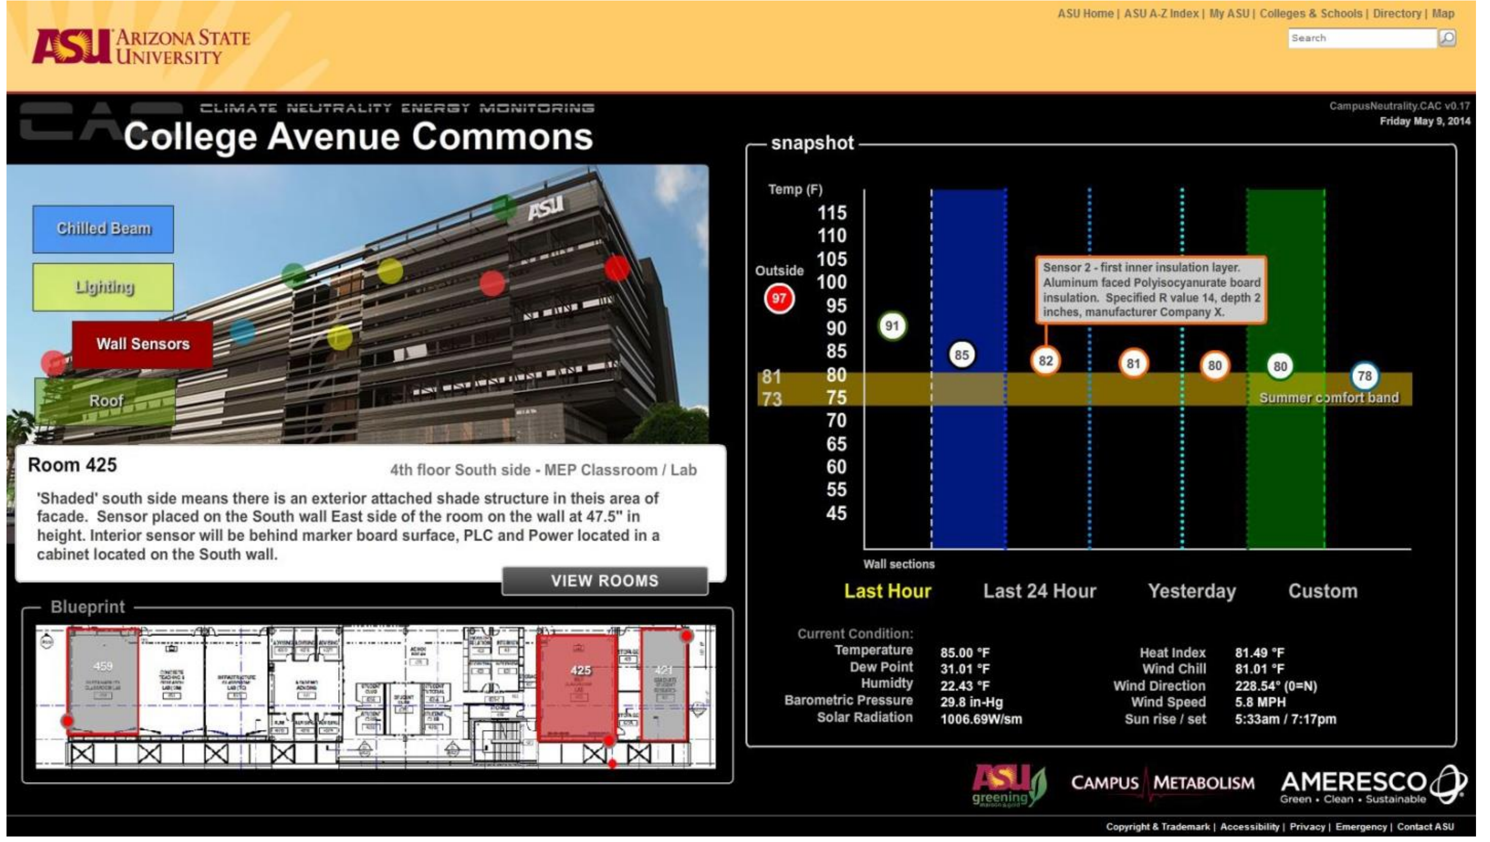

Figure 5 Screen showing Room 425 (highlighted in plan in red) and wall temperature profile

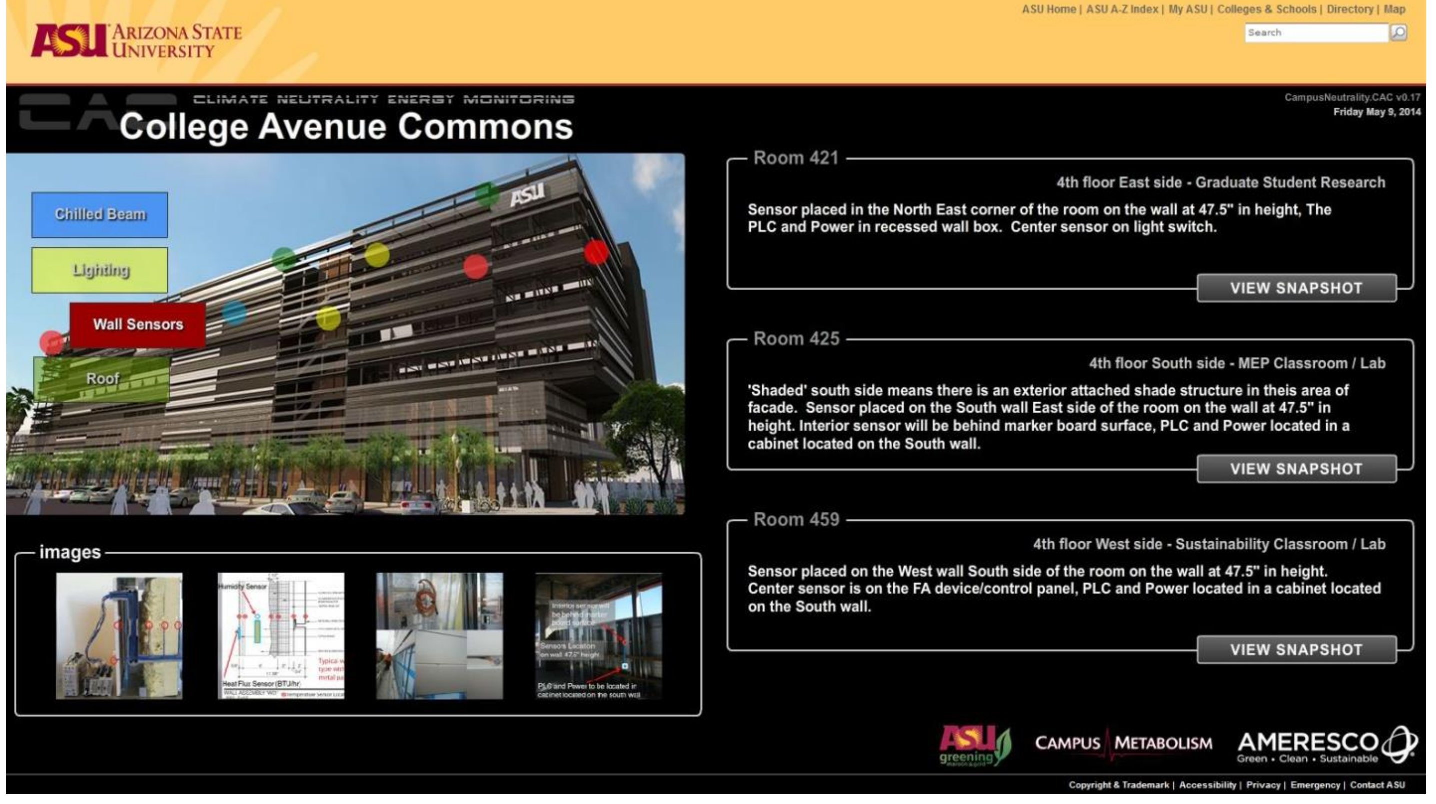

Figure 4 Screen showing the three rooms adjacent to wall sensors and sensor placement (with red dots)

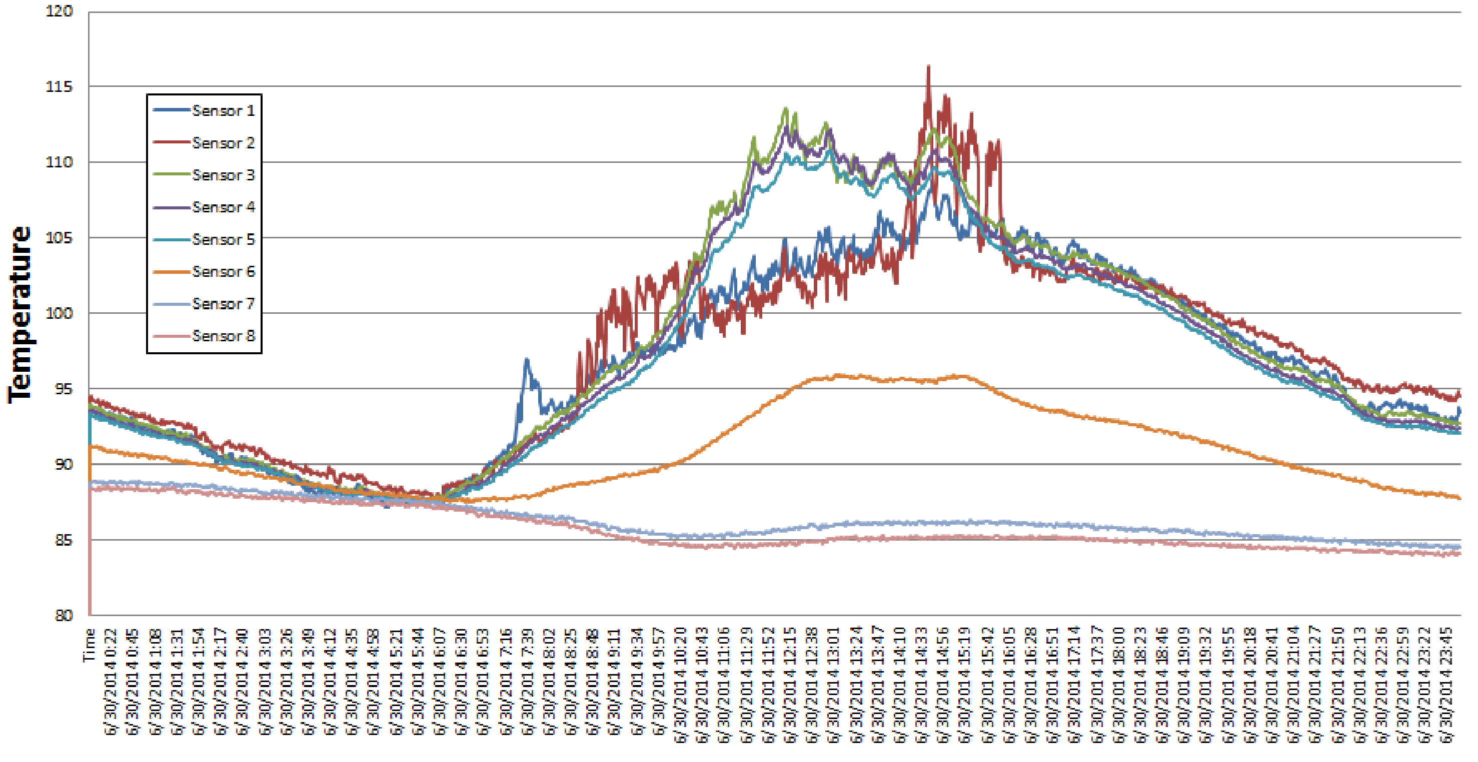

Figure 6 24-hour temperature profile of the eight sensors in the south wall of Room 425 understanding of how building envelopes perform and operate as well as striving for a high level of data transparency. It is hoped that projects like this will give others the information needed to undertake similar installations. By utilizing the Web and presenting data in an interesting and graphically clear manner, it is hoped that it will lead to a host of new and exciting educational outcomes.

ACKNOWLEDGEMENTS

We would like to thank the following individuals; John Kane, Tom Reilly and Johanna Collins from Architekton; Patrick Magness and Mike Stanley from Gensler; and Bill Okland, Tim Goyette and Ryan Johnson from Okland Construction. Without their help this project would not have been completed. We also want to thank, ASU representatives like Morgan Olsen, John Riley, Edd Gibson, Ed Soltero, Patti Olson, Art Lara and Robert Vandling who provided valuable assistance throughout this project. Finally we would like to thank all the subcontractors, manufacturers and tradesmen who worked on the CAC for their time, donations of equipment, support and guidance.

ABSTRACT

Buildings account for 30% of energy consumption in India, and it is estimated that 70% of the projected commercial building stock by 2030 is yet to be built. The recently established five-year US-India Centre for Building Energy Research and Development (CBERD) project aims to address the barriers for adopting low energy consuming strategies in buildings in India, while exploring the lessons that can also be applied to the US context. This paper evaluates the performance of two energy-conscious (EC) and two 'business as usual' (BAU) buildings in Ahmedabad, India using a combination of physical measurements, and a web-based occupant survey. The survey includes questions about Indoor Environmental Quality (IEQ): thermal comfort, indoor air quality, air movement and acoustics; it also asked questions about adaptive controls such as windows and fans.

The EC buildings performed well in many categories compared to the 'business as usual buildings'. One of the EC designed buildings in particular performed exceptionally well compared to the CBE database which consists of over 600 buildings mainly from the US but also from 9 other countries. In the other three buildings, dissatisfaction prevailed mainly with acoustic quality and office layout due to lack of speech privacy and visual privacy, but this is common across the larger database. More than 70% occupants were satisfied with thermal comfort in all except one of the BAU building and of the occupants who were uncomfortable mostly cited air movement being too low as the reason for discomfort.

INTRODUCTION

Building construction is rapidly growing in India, primarily in the commercial sector with office type work. The construction boom, along with the hot climate and increase in purchasing power in metropolitan cities such as Mumbai and Chennai, has led to an unprecedented growth in air conditioner unit sales at almost 20% per year (McNeil and Letschert 2008; Sivak 2009). Studies are being done with Governmental support to evaluate energy efficient ways of providing comfort (Manu et.al. 2012). The Center for Building Energy Research and Development (CBERD) project is a joint initiative of the US Department of Energy and Indo-US Science and Technology Forum that aims to address the barriers for adopting low energy consuming strategies in buildings in India, while exploring the lessons that can also be applied to the US context. In order for low-energy space conditioning strategies to be widely adopted, it is crucial that occupant comfort and well-being are simultaneously maintained or enhanced, and occupant feedback is an invaluable source of information for investigating these impacts. Of particular interest is the use of windows and fans, since air movement is a very cost efficient way of providing comfort.

Occupant feedback is also helpful in diagnosing prevailing issues in a building. For instance, it has been found that in air-conditioned buildings, a large number of occupants are dissatisfied with the temperature in their workspace during summer because it is too cold (Abbaszadeh et.al. 2006; de Dear et.al. 1991). Appropriate action can be taken to address this issue by identifying if there are specific zones in the building that have cold dissatisfaction complaints due to over-cooling. The energy savings accrued by changing the air-conditioning unit setpoint even by few degrees could be significant, especially in warm climates (Hoyt et.al. 2009).

In this paper, we present the results from a post occupancy evaluation of two energy conscious (EC) and two 'business as usual' (BAU) offices using the Center for the Built Environment (CBE) online survey tool and physical indoor temperature measurements. We evaluate the satisfaction in each category and benchmark the performance to the CBE database of 600 buildings. This study is intended to be a pilot for a larger study which will be scaled up to cover buildings with different passive systems in different climates of India.

METHODOLOGY

Building selection

India has a varied range of office building types, starting from those that are purely naturally ventilated to those that are highly energy intensive and use air conditioning throughout the year. This range includes mixed mode buildings that use air conditioning during extreme condtions and operate in natural ventilation mode for the rest of the year. Buildings that may be air conditioned for all twelve months but have efficient system and operation or employ unconventional air conditioning systems also fall in this varied mix of office building typologies. The buildings for this study were selected for the purpose of covering this range as best as possible.

In India, a 'business as usual' office building is likely to have several climate-responsive strategies such as external shading to reduce solar heat gain, interior blinds for controlling glare and visual comfort, operable windows for natural ventilation, and some attention to daylighting. All four of the buildings studied here have these features.

That said, not all Indian buildings have been designed to optimize the performance of these passive features, or to make a conscious attempt with the active mechanical systems to reduce energy consumption. The two buildings in our study that did at least one of these things are being characterized as energy-conscious (EC) design. The other two buildings are being characterized as 'business as usual' BAU, noting again that a BAU building in India will already have more climate-responsive features than its counterpart in the U.S. The wall construction is similar in all four buildings, made predominantly of brick masonry with cement plaster on both sides.

EC-1 is the office of an architecture firm. It takes the approach of relying on passive features to maintain thermal comfort inside and is most likely the least energy intensive out of the four buildings. It was designed to primarily operate in fully naturally ventilated mode, but was later retrofitted with air conditioners following the installation of computers. The building has a high vaulted roof structure over the studios that facilities better ventilation. It has large openings on the north set higher in the building, while the lower openings on south are smaller to reduce direct radiation from entering the space. In the low ceiling areas, clerestory windows provide diffuse daylight across the day. In other places, glass brick is sometimes used to provide diffused daylight. Both the operable windows and pedestal fans are operated by the occupants. The building mass is compact, and the building is partially underground, further reducing the impact of direct radiation. Glazing is approximately 25% of the wall area. The vaulted roofs have an air cavity filled with ceramic fuses (9" long conical pieces mixed with concrete) to provide thermal insulation, and the entire roof is covered with high SRI tile. The immediate surrounding is heavily landscaped with dense trees and water bodies, generating its own microclimate. The building has window air conditioners and operates as a switch-over type mixed mode building where occupants turn off the air conditioner and open the windows when the outdoor conditions are suitable for natural ventilation. The total floor area is spread across four levels, including the mezzanine level. The lower and first floor is occupied by the permanent staff while the mezzanine floor is occupied by temporary staff such as interns and international scholars. 48 of the 54 permanent staff participated in survey, all of them located on lower floor.

EC-2 is a building design and consulting firm. It is a LEED Platinum building, but took an entirely different approach than EC-1 in their energy-conscious design. The firm we studied occupies the seventh floor of a 11-story building that has the usual business-as-usual features described previously. Other than installing double-glazed windows, EC-2 did not attempt to optimize the envelope, but instead reduced their energy consumption by addressing the active systems that serves their air conditioned office space. They have a very efficient HVAC system, demand controlled ventilation, energy-efficient lighting and lighting controls, and occupancy sensors. Like all the buildings in our study, EC-2 has operable windows, but they are not often used by the occupants as the air conditioning is used across the year. There are no interior fans. The wall construction is much more heavily glazed than EC-1 (51-75% of the wall area). In spite of the high WWR and lighting controls, the building seems to rely more on artificial lighting than natural daylighting. The materials used in EC-2 conform to LEED 2.1 specifications such as low VOC paints, coatings, adhesive, sealants and fabrics, green label carpets and cleaning materials. 31 out of the 91 occupants answered the survey.

Both of the following BAU buildings are similar in that they have not made any conscious attempt in either the envelope, active system, or control strategies to reduce energy consumption. However, even without explicit lighting controls, they both rely mostly on natural lighting for the majority of the occupied hours. Both buildings also have ceiling fans (which are not being provided most of the time in newer, sealed buildings in India).

BAU-1 is an office of a computer software developer firm in a heavily urbanized area, located on eighth floor of an 11-story building (similar to EC-2 being on an intermediary floor of a taller building). It is representative of the most energy intensive building with a business-as-usual envelope and air conditioning system and operation. The office has a variable air volume (VAV) type central air conditioning unit that is on throughout the year. The walls are heavily glazed, with the WWR being almost identical to that in EC-2 (51-75% of the wall area). The windows are operable and have a reflecting glass. As in the other buildings, BAU-1 has interior blinds and exterior shading. 27 out of the 140 occupants answered the survey.

BAU-2 is an office of a building construction and MEP consulting firm in a less dense and more vegetated area, located on ground and first floor of an 8-story building. It has a variable refrigerant flow (VRF) type central air conditioning unit, operable windows and ceiling fans. The glazing area is in between the other examples (30-50% of the wall area). The windows have a clear glass, compared to the reflective glazing of BAU-1. While the air-conditioning in BAU-1 operates almost continuously throughout the year, in BAU-2 occupants have a choice to operate it when indoor becomes uncomfortable. 40 out of the 46 occupants answered the survey.

CBE web-based survey tool

The CBE web-based survey tool is an efficient way of remotely getting occupant feedback on indoor environmental quality (IEQ) and various other aspects of the building. Participation in the survey is voluntary and occupants can choose not to answer any question. The questions in the survey were designed after extensive inputs from facility managers and designers so as to report the most useful feedback (Eisenhower 2000). The survey consists of a core module with eight IEQ categories and additional modules such as window and fan usage. Since the surveys were being admisistered in India, the phrasing of the questions and options were tailored to suit the local culture and parlance. The survey asked occupants to rate their satisfaction during summer with these different aspects on a 7-point scale that ranged from -3 (Very dissatisfied) to 0 (Neutral) to +3 (Very satisfied). The tool also has a unique feature that is helpful for diagnostic purposes; when an occupant votes to be dissatisfied in any category, the tool automatically follows up with branching questions that ask about the reasons for dissatisfaction. Details about the building features such as floor area, number of occupants, LEED compliance and type of HVAC system, envelope and glazing are filled out by the building manager separately. More details about the CBE survey tool can be found in (Zagreus 2004). A list of the most relevant survey questions is illustrated in Table 1.

Table 1. Important Categories Included in the CBE survey

Variable	Questions asked
Thermal comfort	Satisfaction with temperature, ability to control temperature, thermal comfort during summer
Indoor air quality	Satisfaction with air quality (i.e. stuffy/stale, cleanliness, odors)
Air movement	Satisfaction with amount of air movement, ability to control amount of air movement
Window usage	Satisfaction with operable windows (summer and winter and monsoon) Importance of having an operable window to the user Times adjusted (daily, weekly, monthly) Time of adjustment Reasons to ‘open’ or ‘close’ a window
Fan usage	Satisfaction with ceiling fans, Times adjusted during summer(daily, weekly, monthly), Time of adjustment, Reasons to turn ‘on’ or ‘off ’ a fan
Acoustics	Satisfaction with noise level and sound privacy

RESULTS

Weather

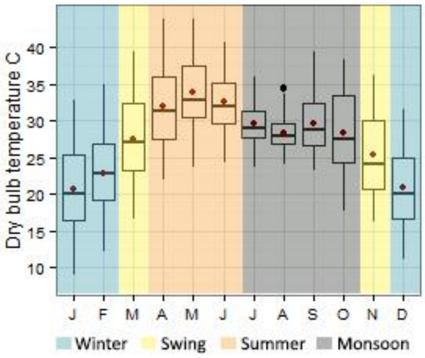

Figure 1. Ahmedabad weather

Figure 1 shows the boxplot of outdoor dry bulb temperature (DBT) based on the ISHRAE weather file (EnergyPlus webpage). Ahmedabad experiences a semi arid climate with predominantly three seasons: summer, monsoon and winter. April to June is the summer season where the mean DBT is above 30 ˚C with a highest recorded value of 44 ˚C. Summers are dry with a mean relative humidity (RH) of 53%. July to October is the monsoon season where the mean monthly DBT is 28 ˚C and mean RH is 70%. November and March are the two transition months with mean DBT of 26 ˚C and mean RH of 47%. December, January and February are the winter months where the mean DBT is comparatively lower at 21 ˚C and mean RH is 52%.

Summary of occupant feedback in all the four buildings

Figure 2 shows the percentile scores compared to the overall CBE dataset, and Figure 3 shows the mean percentage satisfied per survey category in each building (Occupants voting +1 and above were counted as satisfied). In both, green colors designate better performance and orange designates low performance. Figure 2 illustrates that EC-1 (which uses more passive strategies to achieve its energy efficiency) is the best performer of the four buildings, and compared to the CBE database ranked fairly well in most of the survey categories except for ‘office layout’ and ‘air movement’ satisfaction. EC-2 (using improved active systems to achieve low energy consumption) did relatively well in thermal comfort, acoustics, and lighting performance, but ranked low in office layout, air quality and workspace satisfaction. Of the BAU buildings, BAU-1 is the lowest performer of the four buildings across most of the categories, while BAU-2 ranked relatively well in thermal comfort and lighting, but low in air movement satisfaction.

For illustrative purposes in Figure 3, a satisfaction percentage below 70% is assumed to be the threshold for concern. This is more flexible that the conventional 80% satisfaction threshold used in thermal comfort standards, for example. Figure 3 shows that 70% or more occupants were satisfied in EC-1 in all survey categories except for office layout and air movement. It’s interesting to note that even though acoustic satisfaction was in the 95th percentile in Figure 2, this is based on only 78% of the occupants being satisfied, as shown in Figure 3. That is because acoustics generally receives the lowest satisfaction scores in the database, so even 78% is considered quite good, and was also unusually high compared to the other four buildings. The reasons for that are not entirely clear, although the high valuted roof could possibly be a factor. The dissatisfaction with office layout was related mainly with visual privacy (too many people walking around in the work area) and the amount of workspace available for work (this may be due to this being a traditional architecture firm that requires a lot of workspace for paper drawings). The dissatisfaction with air movement prevailed mainly because of the lack of sufficient air movement (rather than air movement being too high), and the inability to control it. However, these complaints were limited to only two zones, D and E. This was surprising since these zones have pedestal or bracket fans, both of which should be adequate to increase air movement close to the person, even more effectively than stratification created by the vaulted roof. This may suggest that even though these fans are available, there are reasons that people are not using them or they are not located properly.

In EC-2, although the building was in the 90^{th} percentile of the CBE database for thermal comfort, this is associated with only 71% of the occupants being satisfactied. This is because this is a pervasive problem in buildings, and thermal issues are usually the #2 complaint (following acoustics). Of the IEQ categories, occupants were most satisfied with lighting, but the highest satisfaction ratings had nothing to do with IEQ (i.e., office furnishings, general building satisfaction, and cleanliness/maintenance). The satisfaction percentage in EC-2 was lowest with acoustics, air quality, office layout and air movement. Lack of sound privacy was the main reason for acoustic dissatisfaction while it was the lack of visual privacy for the dissatisfaction with office layout. A few occupants from EC-2 opined that the air was stuffy/stale, not clean and had a bad odor; the source for bad odor was mainly from the toilets. However, the complaints were limited to one particular zone. With regards to air movement satisfaction, occupants were mainly dissatisfied with amount of air movement (saying they preferred to have more air movement) and the ability to control the amount of air movement. This is not surprising given that this building does not have fans.

BAU-1 is having the biggest challenges with their workplace conditions; less than 70% of the occupants were satisfied in all the categories except for workspace satisfaction, where it was 77% (Figure 3). Higher satisfaction may, in part, be due to this office having relatively low occupant density (10 sq.m. per person, compared to a more typical 6.5 sq.m. per person for India). Amongst the dissatisfied categories, acoustic quality, office layout and thermal comfort were the categories in the lowest satisfaction range; around 50% or less. Similar to EC-2, lack of sound and visual privacy were the main reasons for dissatisfaction with acoustics and office layout respectively. Overall thermal comfort satisfaction was very low in BAU-1 compared to the other three buildings. Those who were dissatisfied cited multiple reasons of discomfort such as incoming sun, air movement being too low and the heating/cooling system not responding quickly to the thermostat.

Occupant response in BAU-2 was in sharp contrast to BAU-1; 70% or more occupants were satisfied with all categories except acoustics (Figure 3). Sound privacy was once again the main source of dissatisfaction. An important point to note with regards to acoustics dissatisfaction in EC-2, BAU-1 and BAU-2 is that occupants were less dissatisfied with noise levels as compared to sound privacy (both of these questions make up the combined metric for acoustic quality); this pattern is common across the CBE database.

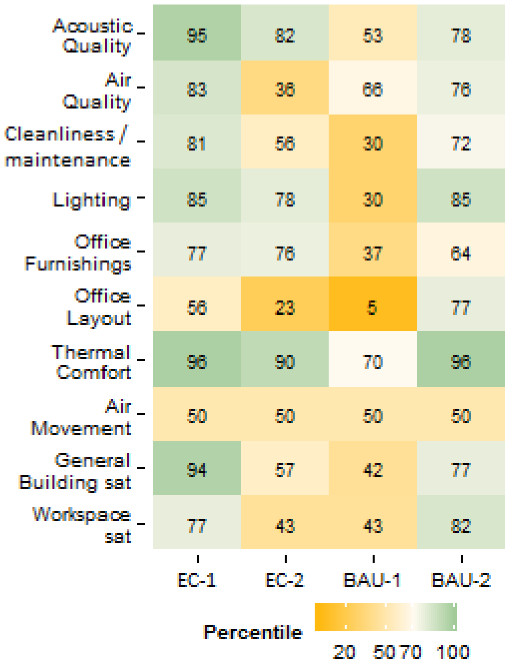

Figure 2. Percentile ranking of the case study buildings compared to the CBE database.

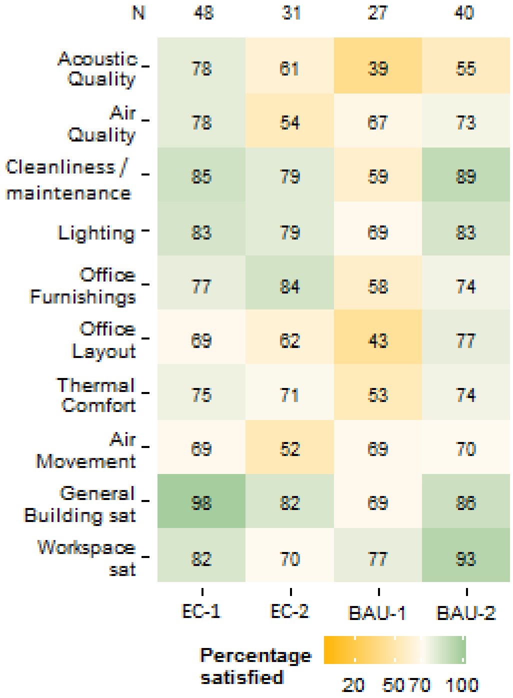

Figure 3. Percentage of occupants satisfied in each case study building

Thermal comfort during summer

Ahmedabad experiences hot summers. Occupants were asked about their thermal comfort opinion 'in general' and specifically during summer. However, to understand thermal comfort during the extreme climate, evaluating thermal comfort satisfaction in summer is more crucial than in general. Using the 7-point satisfaction scale described earlier, Figure 4 (a) – (e) shows the mean thermal comfort response in each zone (labeled alphabetically) of EC-1, EC-2, BAU-1 and BAU-2 respectively (note that BAU-2 has two floors). The color corresponds to the mean value and the numeric is the number of votes in each zone. Figure 5 (a) – (e) shows the distribution of indoor temperature during occupied hours monitored from February – April 2014 in each building. The color and numeric both represent the mean value of indoor temperature while the green dot represents the sensor location.

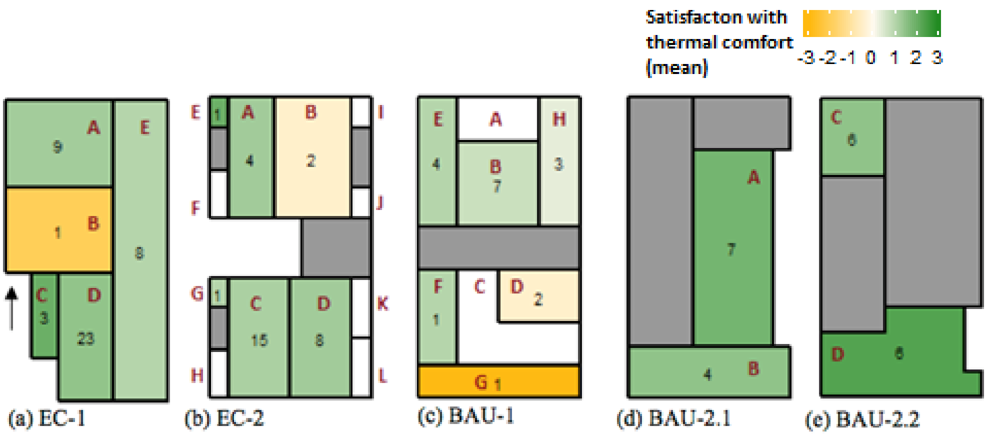

Figure 4. Satisfaction with thermal comfort during summer.
The scale ranged from -3 (Very dissatisfied) to 0 (Neutral) to +3 (Very satisfied)

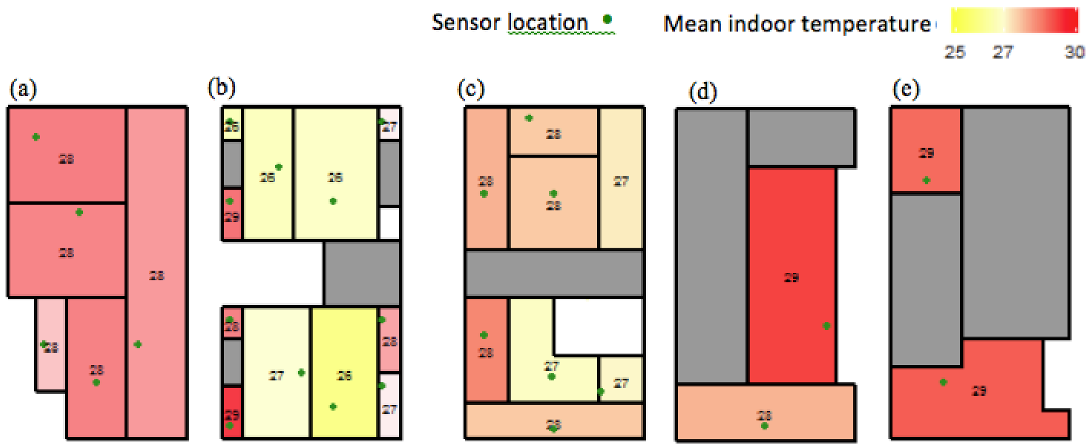

Figure 5. Indoor temperature (°C) between February to April.

More than 70% of the occupants were satisfied with thermal comfort during summer in 3 of the buildings - EC-1 (N=46), EC-2 (N=31) and BAU-2 (N=37) - while only 50% were satisfied in BAU-1. The most cited reason for thermal discomfort in all the four buildings was air movement being too low. The mapping in Figure 4 helps in identifying the zones where the mean satisfaction vote is less than zero. For example, lowest satisfaction occurred in zone B in EC-1, zone B in EC-2 and zone D and G in BAU-1. However, these zones had two or less number of responses and thus these findings are only illustrative, and nothing conclusive can be said.

The mean value of indoor temperature during occupied hours monitored from Februry – March was between 26 – 29 ˚C. The distribution was mostly uniform across all the zones in the building except for EC-2 where the core zones were cooler than the perimeter zones. This could be very likely because EC-2 had the widest floor plate compared to the other three buildings.

In all four of the buildings, occupants voted that room air conditioners and window blinds/shades were the controls that thay were most frequently adjusted. During summer, the majority of the occupants said they either drank something cool or covered the window to keep themselves comfortable.

Window and fan usage

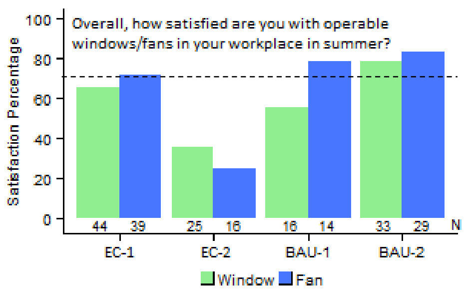

Figure 6. Satisfaction with windows and fans.

Windows and fans are two cost efficient ways of providing comfort in warm climates, and are common in buildings in India. Occupant satisfaction feedback regarding both these adaptive actions is of interest mainly during the summer. Figure 6 shows the percentage satisfied with operable windows and ceiling fans in all four buildings during summer. Looking first at windows, overall, greater than 70% satisfaction with operable windows was only achived in BAU-2. A few occupants from EC-1 said the windows were inaccessible and there were things blocking the window. This was surprising since EC-1 is the building that paid particular attention to using passive, architectural strategies to achieve low energy use. In EC-2, the LEED Platinum building where the focus was more on efficienct active systems, occupants said most of the windows were fixed and in BAU-1 some of the reasons which made it difficult to use windows were the inability to open windows fully and complaints from co-workers. The most frequently cited reasons for opening a window in all the four buildings were, ‘to feel cooler’, ‘to increase air movement’ and ‘to let in fresh air’. Interestingly, the prevailing reasons to close a window were ‘to feel cooler’, ‘outdoor temperature getting warmer than indoors’ (both of these related to having air-conditioning on during a hot day), and ‘to reduce outdoor noise.’ These reasons show that window interaction is driven predominantely by outdoor temperature, air quality and noise levels.

Looking now at fan usage, overall, more than 70% were satisfied with fans during summer in three of the buildings - EC-1, BAU-1 and BAU-2 (the satisfaction with fans was low in EC-2 because the building did not have any). The most cited reasons to turn on a fan in EC-1, BAU-1 and BAU-2 were 'to feel cooler' and to 'increase air movement' while the reason to turn off a fan was to 'reduce air movement' and because 'a co-worker requested it.' These are all as one might expect, and the majority of the occupants in EC-1, BAU-1 and BAU-2 said they were very sure of having the desired effect when they interacted with fans.

DISCUSSION

The occupant feedback surveys revealed that one of the energy conscious buildings (EC-1) was performing well (i.e., it had a satisfaction percentage of above 70% in 8 out of ten categories.) Overall, in all of the buildings occupants were primarily dissatisfied with the acoustics and office layout, which is common across the entire CBE database. Acoustic dissatisfaction is an important area that needs to be carefully evaluated since it is often seen as a potential barrier for natural ventilation. One of the arguments against having natural ventilation in a city like Ahmedabad is that operable windows would bring in outdoor noise. However, the survey results show that occupants were more dissatisfied with sound privacy than noise levels, which has more to do with the open plan layout. In terms of the sources of noise that bothered workers, people talking on phone and overhearing private conversations were the most frequently cited sources of acoustic dissatisfaction, rather than outdoor noise.

Another result worth noting is that all the buildings ranked low in the air movement satisfaction category compared to the CBE database, and the lack of air movement was repeatedly cited as the reason for thermal discomfort. Occupants were also dissatisfied with the ability to control air movement and opined that they needed more of it. This dissatisfaction prevailed mainly in zones that did not have fans, which means more attention needs to be given to providing sources of air movement in these buildings. Amongst those who had fans, the main reasons to turn on a fan were to feel cooler and increase air movement. Moreover, when asked about the confidence of having the desired effect on turning on a fan, the majority of the occupants voted that they were confident about this effect. This shows that occupants perceive fans as fast-acting and they rely on it for achieving comfort in a short span of time. Windows on the other hand were opened to let in fresh air in addition to feel cooler and increase air movement. There was a consistent opinion about the reasons to close a window, i.e. when the outdoor got warmer than the indoors. The key take-away from this result is that the occupants prefered to have air movement and when there was a combination of windows and fans in use, they worked well in providing it.

The results also revealed an interesting aspect of occupant satisfaction in EC and BAU buildings. Given that BAU-2 performed better than EC-2, this indicates that one cannot necessarily conclude that a building designed for better energy efficiency will result in better occupant satisfaction as well. In addition to needing to pay more attention to air movement and other indoor environmental factors, there could possibly be latent factors such as interior layout, work culture, and connection to the outdoor views that are important (all of these were better in BAU-2).

This study is a pilot for further research where surveys will be conducted across buildings in different climates of India. Although spatial mapping of thermal comfort and temperature is a powerful method of diagnostics, we were not yet able to generalize about the impact of relevant building design issues due to the uneven distribution of the number of responses (i.e., zones where occupants voted to be dissatisfied with thermal comfort had very few votes.) The scaled up study will consider ways by which we will ensure a minimum number of responses from each zone.

CONCLUSIONS

Indoor Environmental Quality (IEQ) parameters were evaluated in two energy-conscious (EC) and two 'business-as-usual' (BAU) buildings in Ahmedabad. The EC building that utilized more passive architectural approaches performed well in most of the categories compared to the buildings in the CBE database, the other three buildings had multiple categories of concern. Overall, the occupants expressed maximum dissatisfaction with sound and visual privacy. They were mostly satisfied with thermal comfort except in one BAU building. Those who were dissatisfied most frequently cited 'air movement being too low' as the reason for dissatisfaction. In buildings that had fans, it was perceived to be a fast acting way of providing comfort. Fans were operated mostly due to thermal and air movement needs while windows were operated due to indoor air quality and acoustic reasons in addition to the two former reasons.

ACKNOWLEDGEMENTS

This study was funded by the US – India Joint Clean Energy Research and Development Center (JCERDC) under the framework of the Center for Building Energy Research and Development (CBERD) project supported by the US – India Science and Technology Forum and the U.S. Department of Energy. We thank Margaret Pigman, Caroline Karmann and David Lehrer from CBE for their feedback on this paper, Joan Tionko from CBE for her help with administering the surveys and Krishna Shah from CEPT for her help with physical data monitoring.

ABSTRACT

Free-running buildings (i.e. naturally ventilated buildings with no mechanical systems for heating or cooling) have the potential to be much more energy efficient than air-conditioned buildings. This paper is based on approximately 3200 instantaneous thermal comfort and 1500 long term background survey datasets from a large scale field study conducted in free-running Indian office buildings. Responses to air movement satisfaction and air movement preference questions, together with concurrent measurements of indoor environmental parameters of air and globe temperature, relative humidity and air velocity are used for this study. The paper gives an insight into the operation of ceiling fans and windows, and the range of air velocity experienced by office workers in free-running office buildings. It gives the relationship between measured indoor air velocity, concurrent air and globe temperature and relative humidity. Instantaneous responses are correlated with the on-site observations on window and ceiling fan operation, as well as indoor environmental measurements. The assessment of preferred air velocity from ceiling fans and operable windows as an adaptive measure in this paper contributes to the development of better designed free-running office buildings in India.

INTRODUCTION

India is a rapidly growing economy with a population of more than 1.2 billion which marks 17.6% increase in 10 years. According to the Indian Census of 2011, the country has about 46 cities with population of over 1 million (Census Organization of India) and many more cities will join this list in a matter of a few years. People need buildings to live and work. The growth in population, therefore, is linked to the rapid increase in building construction and infrastructure demand. Building construction and operation requires energy, for most part, in the form of electricity. Coal, a non-renewable resource, is the primary source of electricity in the country. To sustain the GDP growth at 7-8% (projected average), energy security must be ensured. On the other hand, global climate change and the environmental degradation points to the need to chart a more responsible growth path. It is clear that in the current scenario of climate change, energy efficiency in buildings is the most important 'energy source' for India.

The primary end use of electricity in buildings is to provide thermal comfort to occupants through air conditioning. It is therefore important to focus on what constitutes thermal comfort for people in buildings. ASHRAE defines it as 'a state of mind that expresses satisfaction with existing environment'. It also precribes standard thermal comfort conditions for air conditioned and free-running buildings (ASHRAE, 2010). In India, the National Building Code (Bureau of Indian Standards, 2005) provides construction guidelines, administrative regulations, development control rules and general building

requirements related to fire safety, materials, structural design, plumbing and building services. The Energy Conservation Building Code of India (Ministry of Power, 2007) prescribes minimum standards for energy efficiency in buildings, soon to be mandated across the country. None of these codes propose an explicit thermal comfort model for India. Some individual researchers have worked in this area but their work is limited to residential studies in selected regions of the country (Singh, Mahapatra, & Atreya, 2011; Indraganti, 2010). The dearth of extensive field studies to understand thermal comfort in offices across all climate zones of India led to the conception of the India Model for Adaptive Comfort (IMAC) study in 2011 (Manu, Shukla, Rawal, de Dear, & Thomas, 2014 forthcoming). The primary objective of this study was to develop an adaptive thermal comfort model for India.

This paper presents a part of the IMAC study, focusing on the role of air velocity in the thermal comfort sensation of building users. Adjusting local air velocity through the use of ceiling fans and/or windows is one of the most significant behavioral adaptation mechanisms. Studies show that the building occupants use this mechanism in warm or warm-humid conditions to achieve comfort. Nicol (1974) reported a reduction in thermal discomfort at 32-40 ˚C at air velocity >0.25 m/s in regional studies in India and Iran, supplemented by similar findings from Sharma and Ali (1986). Field studies in the sub-tropical climate of Hong Kong indicate that air velocity of 1.0-1.5 m/s would likely satisfy 80% of the occupants thermally in summer season and that with 1.5 m/s air velocity, the upper limit of comfort temperature reached 33.5 ˚C (Cheng & Ng, 2006).

Studies have also indicated the need for increase in air velocity even in air conditioned buildings to offset increase in temperature (Arens, Turner, Zhang, & Paliaga, 2009). Feriadi (Feriadi & Wong, 2004) reports the tendency of the occupants to modify the hot and humid living environment by turning on fans and opening the windows. Field studies in the warm and humid climate of Bangladesh show an increase in comfort temperature with air velocities greater than 0.3 m/s (Mallick, 1996).

METHODOLOGY

The analysis presented in this paper is based on the data collected over four campaigns of surveys in office buildings in India, spanning a period of one year. These surveys were administered in five Indian cities selected as representative locations for the five climate zones prevalent in India – warm & humid, hot & dry, composite, moderate and cold. In order to document a wide range of indoor environmental conditions, surveys were administered in naturally ventilated, mixed-mode and air conditioned buildings in these five cities during summer, winter and monsoon seasons. The instantaneous thermal comfort surveys (TCS), which were repeated every season, gathered responses related to thermal sensation, preference and acceptability, air movement satisfaction and preference, clothing and activity. These were accompanied by simultaneous measurement of the indoor climatic parameters – air temperature, globe temperature, relative humidity and air velocity. Building Use Studies (BUS) methodology (Building Use Studies Ltd., 2014) was also used as a post-occupancy evaluation tool to gather long-term responses (Leaman, 1995). It has questions framed to draw responses to the workspace environment on a seasonal basis from past experiences of the respondents. The questionnaire covers aspects such as thermal comfort, ventilation, lighting, noise, indoor air quality, personal control. A total of 6330 TCS and 2002 BUS responses were gathered from 16 buildings under the IMAC 2014 project. Of these, 2005 TCS and 652 BUS responses are from occupants in buildings that were naturally ventilated throughout the year and constitute the data set analyzed in this paper.

In the IMAC study, buildings that did not have any mechanical cooling or air-conditioning systems installed and had ceiling fans and operable windows, were classified as pure naturally ventilated (NV) buildings. Survey responses from NV buildings have been separated from those of the mixed-mode buildings working in naturally ventilated mode at the time of the survey (NV_{mm}). Even though the indoor conditions follow the outdoor in both NV and NV_{mm}, the premise for this distinction is that subjects in NV_{mm} mode experience AC (air conditioned mode) for a part of the year and, therefore, may have different responses to, and expectations from, the thermal environment of the work space, as compared to those who never experience AC at work. This classification was done during the analysis of the study and it was found that none of the buildings in the composite climate zone could be categorized as NV.

The present paper focuses on the seven NV buildings, one each in the hot and dry zone (HD1) and warm and humid (WH1), two in moderate (MD1, 2), and three in cold (CD1-3) climate zone (Table 1).

Table 1 Survey schedule and number of responses

Building		TCS Summer responses (Month)	TCS Monsoon responses (Month)	TCS Winter responses (Month)	BUS responses (Month)
HD1	Ahmedabad	137 (May)	121 (Jul)	167 (Jan)	123 (Jul)
MD1	Bangalore	38 (May)	48 (Aug)	33 (Jan)	46 (Aug)
MD2		132 (May)	149 (Aug)	127 (Jan)	138 (Aug)
WH1	Chennai	90 (Jun)	85 (Oct)	104 (Jan)	98 (Oct)
CD1	Shimla	64 (Jun)	68 (Aug)	69 (Dec)	68 (Aug)
CD2		120 (Jun)	126 (Aug)	111 (Dec)	108 (Aug)
CD3		83 (Jun)	72 (Aug)	61 (Dec)	71 (Aug)
Total		**664**	**669**	**672**	
			2005		**652**

Note: HD = hot and dry; MD = moderate; WH = warm and humid; CD = Cold

Table 2 Study parameters and scales used

Parameter	Scale						
Thermal comfort field studies (TCS) 'Right Here, Right now'							
Thermal sensation	Hot (+3)	+2	+1	Neutral (0)	-1	-2	Cold (-3)
Thermal acceptance	Unacceptable (1)			Acceptable (2)			
Thermal preference	To be warmer (1)			No change (2)			To be cooler (3)
Air movement satisfaction	Unsatisfactory (1)	2	3	4	5	6	Satisfactory (7)
Air movement preference	More air movement (1)			No change (2)			Less air movement (3)
Fan operation	OFF (0)	ON (1)		Not available (N/A)			
Window operation	Shut (0)	Open (1)		Partially open (2)		Not available (N/A)	
Building Use Studies (BUS) long term survey							
Air stillness	Still (1)	2	3	4	5	6	Draughty (7)
Air quality	Unsatisfactory (1)	2	3	4	5	6	Satisfactory (7)

Three responses related to thermal sensation, acceptance and preference, and two responses related to air movement satisfaction and preference from TCS were used for the analysis. From BUS, responses to the fields related to air stillness and satisfaction with the overall air quality were included. Status of fans and windows for each survey response was also recorded. The scales and values for each of these variables are given in Table 2.

RESULTS

Indoor Climate

Air velocity in naturally ventilated buildings is primarily a function of cross ventilation by opening of windows or the use of ceiling fans. In the NV dataset, the mean indoor air velocity observed was around 0.2 m/s (range = 0-1.96 m/s; SD = 0.4) across all seasons and climate zones. Figure 1 plots the mean, maximum and minimum air velocities for each climate zone-season aggregate for NV buildings. Of the four climate zones, the highest mean air velocity of 0.6 m/s was observed in warm and humid zone in monsoon and summer, and maximum air velocity of 1.96 m/s in monsoon, the highest of all other zones. This can be explained by greater use of ceiling fans or windows to reduce the discomfort resulting from high humidity and temperature. Hot and dry climate zone also presented trends of high values of mean and maximum air velocity. There was almost no variation in mean air velocity in cold climate zone. This is because ceiling fans were not available in any of the buildings surveyed and are not a common feature in buildings in cold climate. Across all climate zones, the highest mean air velocity occurred in summer (0.3 m/s) and the lowest in winter (0.1 m/s).

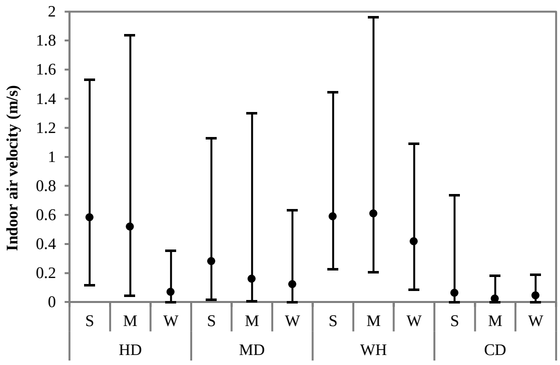

Figure 1 Prevalent air velocities in NV buildings in different seasons and climate zones (S=Summer; M=Monsoon; W=Winter)

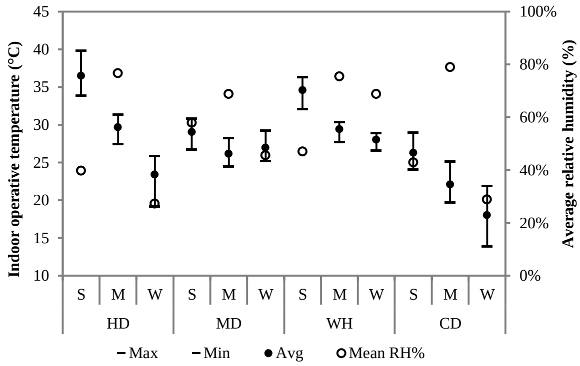

Figure 2 Prevalent indoor operative temperatures and relative humidities in NV buildings in different seasons and climate zones (S=Summer; M=Monsoon; W=Winter)

Comparing Figure 1 and Figure 2, it may be observed that the indoor operative temperature trends were followed closely by the mean air velocity trends – air velocities increased exponentially with increase in indoor operative temperature, till about 30 ˚C, beyond which there was no change. It was, however, difficult to relate mean air velocity with the variation in mean relative humidity. This may indicate that the increase in mean air velocity as an adaptive measure was, in most instances, related to adapting to high indoor temperature rather than high humidity levels.

Figure 3 plots the mean, maximum and minimum air velocities with respect to the mean indoor operative temperature. In the range of 21.5-29.5 ˚C, the relationship was best explained by expressing indoor air velocity as an exponential function of indoor operative temperature, explaining 80% of the variance in air velocity in NV buildings. Mean air velocities at indoor operative temperatures less than 21.5 ˚C were constant at 0.05 m/s and those at temperatures greater than 29.5 ˚C were constant at 0.6 m/s. This may be indicative of the limitations of changing the air velocity as an adaptive mechanism for very high or low indoor temperatures. Figure 4 examines the relationship between mean air velocity and outdoor 7-day weighted running mean air temperature. The exponential function explained 47% of the variance in air velocity with outdoor temperature. The relationship, however, was not as strong as in the case of indoor operative temperature in Figure 3.

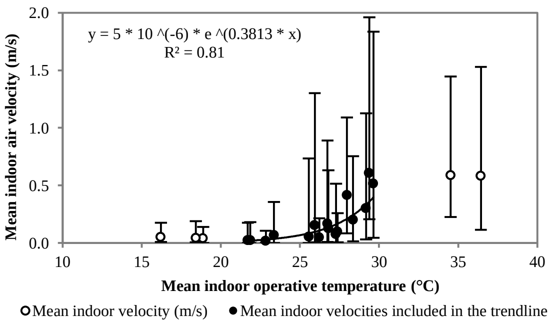

Figure 3 Variation in air velocity with indoor operative temperature

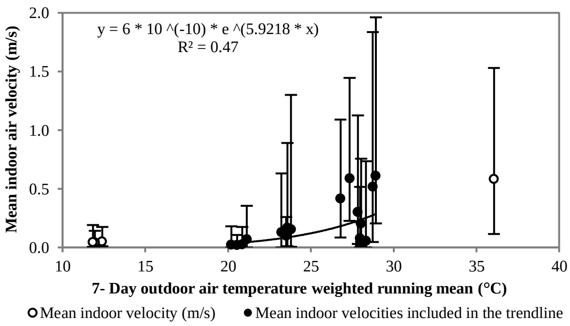

Figure 4 Variation in air velocity with outdoor air temperature

Adaptive opportunities: status of fans and windows

For almost all survey responses, fans were observed to be ON during all three seasons in the warm and humid climate (Figure 5). This may be to alleviate discomfort due to high temperatures in summer and high humidity levels in monsoon and winter. In hot and dry zone, almost all fans were reported to be ON in summer and monsoon and almost all were OFF in winter.

A more mixed use was observed in the moderate climate zone where fans were ON in 80% instances in summer and almost 25% in monsoon and winter. Cold climate zone did not have any fans available, except for a small fraction of 4-10% owing to isolated cases of table/wall mounted fans. Window use was highest in hot and dry and warm and humid climate zones in monsoon with 71-78% responses indicating open windows (Figure 7). 45-60% of the responses reported open windows in summer, across all climate zones. For monsoon and winter, however, the variation was greater.

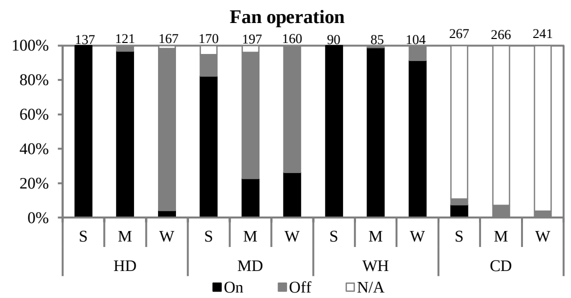

Figure 5 Status of ceiling fan operation in NV buildings in different seasons and climate zones

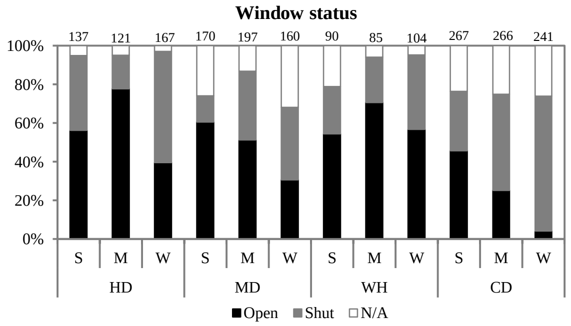

Figure 7 Status of window operation in NV buildings in different seasons and climate zones

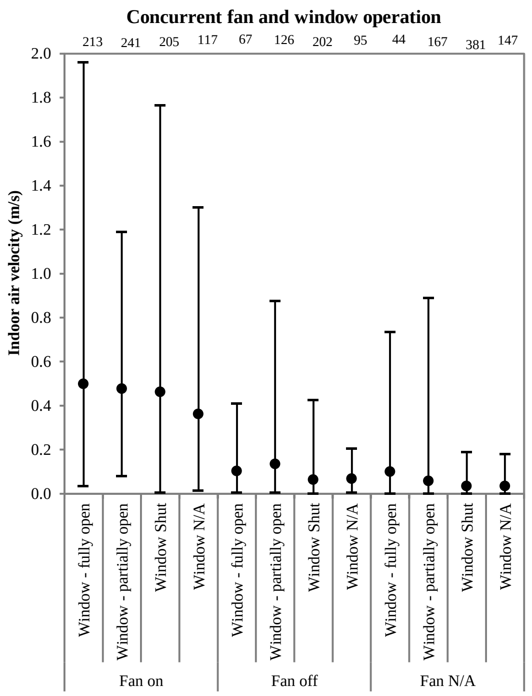

Figure 6 Status of concurrent operation of ceiling fans and windows in NV buildings in different seasons and climate zones

Figure 6 superimposes mean air velocity with fan and window operation. It clearly indicates that window use had little effect on mean indoor air velocity. When the fans were OFF or not available, opening or shutting the windows led to prevalent mean air velocities ranging from 0.06-0.13 m/s. On the other hand, when windows were shut or unavailable, operation of fans induced mean air velocities ranging from 0.36-0.46 m/s. In warm and humid zone, more than 90% fans were ON in all seasons. In hot and dry zone, almost 100% fans were ON in summer and monsoon.

In Figure 8, indoor operative temperatures were binned at 0.25 ˚C and percentage of fans and windows in operation was calculated for each temperature bin. A logit curve best explained fan operation with change in indoor operative temperature. It indicates that percentage of fans in ON mode increased exponentially with increase in indoor operative temperatures. When indoor operative temperatures were higher than 31 ˚C, all fans were ON and almost 90% of the fans were OFF below 25 ˚C. Figure 8 also shows window operation was used as an adaptive measure till the indoor operative temperatures reached 32 ˚C at which point all windows were open. Beyond 34 ˚C, occupants seemed to be shutting the windows, again as an adaptive measure to avoid excessive heat ingress from outdoors into their workspaces. A polynomial trend line (R^2=0.66) was used to capture occupant behavior more closely with actual operation. The polynomial curve, however, was still not able to explain the instances where all windows were open. A linear trend line (R^2=0.79) was then used which was able to explain window operation till 32 ˚C of indoor operative temperatures. Within this limit it indicated a significant relationship showing that with every 1 ˚C increase in indoor operative temperature, the proportion of open windows increased by 5%.

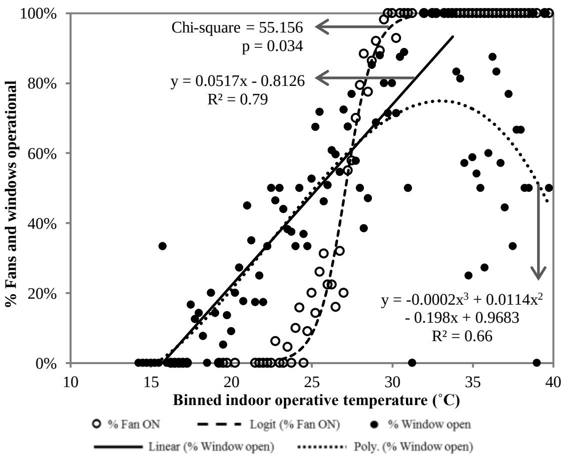

Figure 8 Proportion on fans and windows in use in NV buildings expressed as a function of indoor operative temperature

The figure establishes the use of fans and windows to alleviate discomfort owing to high indoor temperatures. It also indicates the level of indoor thermal conditions at which these adaptive measures were used. This provides a critical piece of information regarding occupant behavior that is important for building energy simulation but has not been available for workspaces in India.

Impact of air movement on thermal comfort

It is evident from Figure 9 that 65% of the people who voted neutral for thermal sensation also voted for no change in air movement. Almost 70% of people who voted ‘hot’ (+3) on the sensation scale preferred more air movement. Percentage of responses voting for no change in air movement decreased towards both ends of the sensation scale (hot and cold). The preference for more air movement, however, increased as the sensation votes moved towards +3. 57% of the people feeling ‘slightly cool’ preferred no change but a staggering 40% wanted more air movement. In Figure 10, almost 70% of the respondents voting for no change in the thermal environment did not want any change in the air movement. 65% of the people who wanted to be cooler also preferred to have more air movement. This agrees with the general idea that in an uncomfortably warm environment, people tend to want high air velocity as an adaptive measure. It is interesting to note, however, that more than 40% of people who were feeling cooler than normal (wanted warmer) also wanted more air movement even though more air movement would make them cooler than they felt. Almost 60% of the people who found their thermal environment unacceptable voted for more air movement (Figure 11). About the same ratio wanted no change in air movement among those who voted the thermal conditions as acceptable. Almost 43% of the respondents in NV buildings wanted more air movement and 3% wanted less air movement.

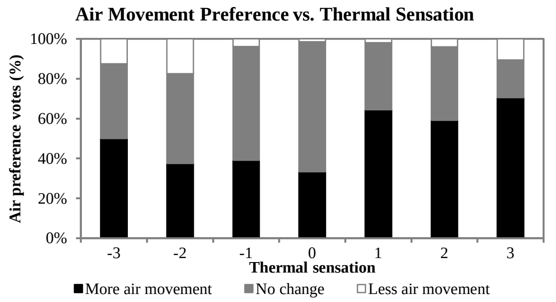

Figure 9 Distribution of air movement preference votes on the thermal sensation scale

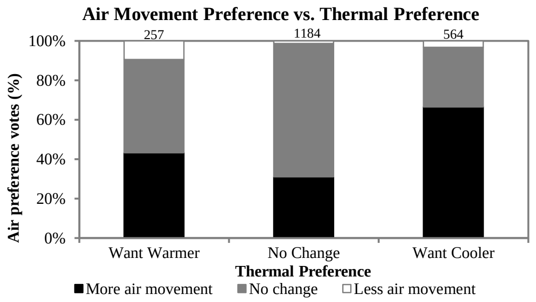

Figure 10 Distribution of air movement preference votes across thermal preference response categories

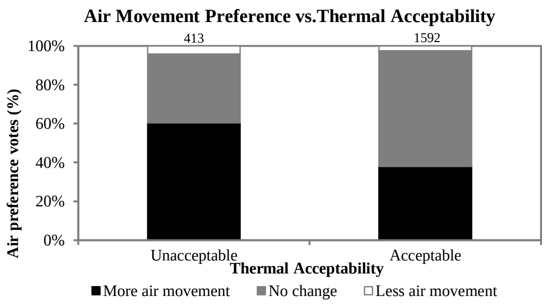

Figure 11 Distribution of air movement preference votes across thermal acceptability response categories

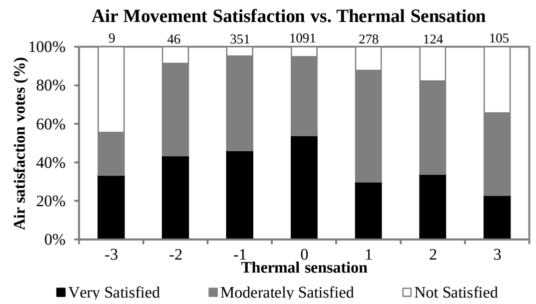

Figure 12 Distribution of air movement satisfaction votes on the thermal sensation scale

In order to assess air movement satisfaction, the 7-point scale from Table 2 was converted into a three-point scale by merging the responses in the first two categories into one ‘not satisfied’ category and merging the last two into ‘very satisfied’. The central three categories formed ‘moderately satisfied’. The number of votes (%) was then plotted against thermal sensation (Figure 12). Among the subjects who voted for neutral thermal sensation, 54% were very satisfied, 41% were moderately satisfied and 5% were dissatisfied with air movement. The percentage of dissatisfied respondents increases as the sensation moves towards ±3 vote. Almost 35% of the respondents voting ‘hot’ are dissatisfied with the air movement. Interestingly, this percentage increases to 45% for those voting ‘cold’. 60% subjects who did not want to change their thermal environment were moderately satisfied with the air movement.

Almost 85% of the people who were very satisfied with the air movement did not want any change but 15% wanted more air movement (Figure 13). This suggests a discrepancy between air movement satisfaction and preference. Of those who were moderately satisfied with the air movement, 60% wanted more air movement. It is important to note, however, that 95% of the subjects not satisfied with air movement wanted more air movement in the work space.

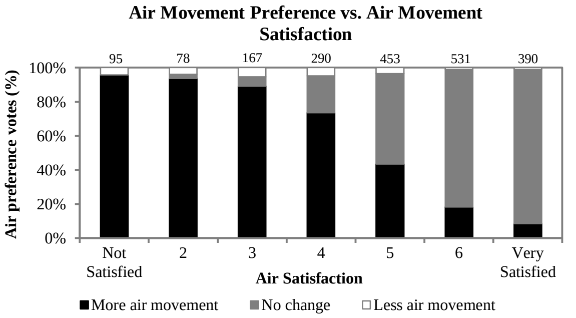

Figure 13 Distribution of air movement preference votes on the air movement satisfaction scale

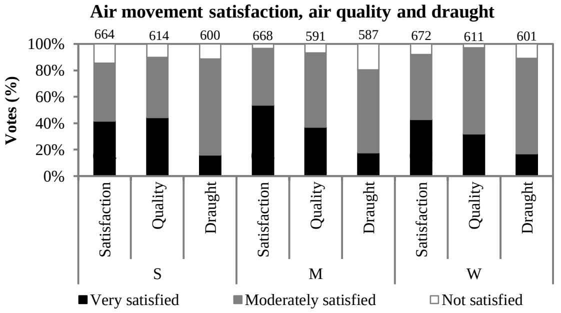

Figure 14 Comparison of air satisfaction votes from TCS with the air quality satisfaction and air draught votes from BUS

Reponses related to overall air quality and draught from the BUS questionnaire were compared with air movement satisfaction (Figure 14). It is important to note here that the BUS survey was administered in the seven NV buildings in the monsoon season. So, the responses to air quality and draught for summer and winter seasons were based on respondents' memory of their experiences related to these aspects of the work space. Draught does not seem to be a problem in the NV buildings, with only 10-20% of the subjects interviewed reporting draught across three seasons. Almost 60-70% responses indicated that the workspaces were moderately draughty. Reponses to the question of air quality satisfaction indicate 30-45% subjects being very satisfied and 45-65% being moderately satisfied. Maximum dissatisfaction responses of 10% occur in summer season.

CONCLUSION

The results from the study revealed the range of air velocities prevalent in NV office buildings in India, reaching as high as 2.0m/s. Indoor air was nearly still (average air velocity < 0.1 m/s) in cold climate zones across all seasons. Mean air velocities in all seasons in warm and humid zone were highest (0.4-0.6 m/s) as compared to other climate zones. They were closely related to the indoor operative temperatures and increased exponentially from 22-30 ˚C. Below 22 ˚C, mean air velocities were less than 0.1m/s and above 30 ˚C indoor operative temperatures, they were constant at 0.6 m/s. This indicated that high air velocity was used as an adaptive measure to address discomfort due to indoor warmth rather than humidity. There was a strong relationship between mean indoor air velocities and indoor operative temperatures. The dependence of mean air velocities on outdoor warmth, however, was not very robust.

Fans and windows are very important adaptive measures for subjects working in naturally ventilated spaces. That said, higher air speeds were primarily a contribution of fans (0.3-0.4m/s) and windows had a limited role (<0.06 m/s) to play. One may suggest that more than the need for higher air movement, windows were opened for other reasons such as cooling the indoors (when outdoor is pleasant), fresh air, daylight and view.

Window use also showed a very robust correlation with indoor operative temperature explained by a linear trend till 32˚C indoor operative temperature. Occupants started operating windows when the indoor operative temperatures reached 15 ˚C. All windows were open between 32-34 ˚C and closed again when temperatures approached 34 ˚C. The logit regression predicted that ceilings fans started operating at 23 ˚C and 100% of the fans were in use at 31˚C and higher indoor operative temperatures.

The study also shows that the office workers in India tend to prefer more air movement, or higher air velocities. Even when they found the thermal environment acceptable, almost 40% wanted more air movement. Respondents' dissatisfaction with air movement was primarily due to the lack of it. Air movement preference and satisfaction were closely related to thermal sensation. Subjects preferred more air movement as the sensation moved towards the either end (+3 and -3) of the 7-point sensation scale. At +3, 70% respondents wanted more air movement and at -3 the percentage of respondents wanting more air movement was 45%. Even when subjects were cooler than they would like, they wanted higher air movement.

Most importantly, the study provided valuable insights into occupant behavior in office buildings. Some of the results from this study could be used to better inform the simulation models that are usually very different from the real buildings. The results give very clear indications of how fans and windows are operated in naturally ventilated office buildings and could help build operation schedules for building energy simulation.

ACKNOWLEDGEMENTS

The authors would like to thank the Ministry of New and Renewable Energy, Government of India, and Shakti Sustainable Energy Foundation for funding this study. They are grateful to all the survey respondents and managers/owners of the buildings that were surveyed. The authors would also like to acknowledge all the field researchers for their extensive work at data collection.

ABSTRACT

All too often today's buildings require massive resource input. The way we define the "comfortable" thermal conditions play a significant role in this environmental impact and the systems and energy required to air condition and cool our buildings. Adaptive comfort models, developed on the basis of field studies in tropical and subtropical climates, give evidence that extended operative temperature and humidity ranges are acceptable for indoor climate especially when combined with elevated air speed controlled by the occupants. Adaptive comfort typically can be achieved with less mechanical systems. The aim of this paper is to propose a low-energy, hybrid system design method as an alternative design strategy to "static" and deterministic HVAC control systems. In this context adaptive is not about changing people's comfort expectations, it is about changing environmental conditions, especially the air speed, to create comfort and to compensate for higher temperatures and humidities.

The non-governmental organization BRAC is planning a new university building in Dhaka, Bangladesh. To reduce resource consumption, technical systems and energy demand the design team is investigating alternative comfort strategies. The paper presents the design strategy, implementation in building simulation and analysis of thermal comfort concepts for a typical classroom. A conventional design for air conditioning according the static "comfort zone" is compared to a hybrid system design in regard to achieved comfort, required design of ventilation systems and energy demand. The thermal parameters of the building are assessed using the dynamical thermal simulation program TRNSYS 17 3D. Based on six environmental parameters the thermal comfort of the occupants is evaluated with the Standard Effective Temperature (SET) and the Predicted Mean Vote for elevated air speed (PMV_{eas}) according to the ASHRAE Standard 55-2013.

The design studies helped to develop a hybrid system comfort design which provides good fresh air quality and an excellent thermal comfort: A simple decentral mechanical system provides the room with tempered supply air of 20°C air temperature and dew point. In addition, ceiling fans provide air movement. Compared to conventional concepts of returned air with full heat recovery aiming on 26°C operative room temperature and 12 g/kg humidity ratio the energy demand is only about 75%. Both concepts provide the same comfort in terms of PMV_{eas}.

INTRODUCTION

Thermal comfort standards e.g. of ASHRAE [1] and ISO [2] are dominated by the studies and heat balance model works of O. Fanger, using the *Predicted Mean Vote (PMV)* as comfort index. Being carefully developed in mid-latitude climate regions systematic discrepancies were found, particularly in warmer zones, to explain observed thermal comfort in naturally ventilated buildings with the static "comfort zones" definitions based on the six comfort parameters in Fanger's PMV model [3]. Adaptive comfort models, developed on field studies in the tropics, as well as comparing naturally ventilated and air conditioned buildings give evidence that extended temperature and humidity ranges are acceptable [4].

Elevated air speed has long been used in practice as well as in the ASHRAE Standard 55 to offset higher temperatures in mechanically controlled indoor climates. With ASHRAE Standard 55-2013, Appendix G, a procedure for evaluating the cooling effect of elevated air speed using the *Standard Effective Temperature (SET)* is described. The *SET* can be calculated for a wide range of six environmental and personal parameters: *air temperature (T_{air}), mean radiant temperature (MRT), relative humidity (RH), average elevated air speed (v), clothing factor (clo) and metabolic rate (met).*

To evaluate the cooling effect of elevated air speed first the *SET* is calculated for the parameters and the given air speed (range: $0.15 \leq v \leq 3$ m/s). In a second step the air speed is replaced by still air (0.15 m/s) and an adjusted average air temperature is calculated to achieve the same *SET* as before. With this adjusted average air temperature, the air speed of still air and the four remaining parameters the *Predicted Mean Vote for elevated air speed (PMV_{eas})* is calculated and can be used for comfort evaluation and comparison [1, Appendix G and B]. This procedure was implemented into building simulation. To be useful for the evaluation and design of alternative comfort and climate concepts the method is implemented in a way that the required air speed to create the same perceived comfort - or in other words the same *Predicted Mean Vote for elevated air speed (PMV_{eas})* as for the reference case - could be determined by the simulation code representing an occupant controlled fan to increase air speed as required. An exemplified tool including PMV_{eas} is the Internet CBE Thermal Comfort Tool developed at the University of California Berkeley [5].

To summarize: the implemented procedure allows evaluating the different design strategies with the 7-point scale of thermal sensation, defined as follows: hot (+3), warm (+2), slightly warm (+1), neutral (0), slightly cool (-1), cool (-2), cold (-3) and compare with the analytical comfort zone model of Standard 55-2013, chapter 5.3.2. Compliance is achieved when $-0.5 < PMV_{eas} < 0.5$, which is equivalent to a satisfaction of 90% of the occupants with the environmental conditions.

THE PROJECT

The non-governmental organization BRAC is currently planning a new university building in Dhaka, Bangladesh. BRAC is particularly interested in a sustainable building concept which creates best comfort in the local context. The architects commissioned are WOHA, Singapore, who are experienced in the design of naturally ventilated buildings in the tropics. For comparison study, the School Of The Arts (SOTA) in Singapore, also designed by WOHA Architects, serves as a role model: Wherever appropriate, the classrooms are naturally ventilated and thermal comfort is enhanced with ceiling fans to elevate air speed in the occupied zone. The passive building design and the elevation of the classrooms above ground reinforce natural ventilation by prevailing wind directions. Air conditioned zones are reduced to a minimum.

To cross check the proposed design strategy and to familiarize the design team with the strategy evaluating thermal comfort with the *SET* and *PMV_{eas}* a short comfort survey was made at SOTA. The classroom (Figure 1) was surveyed for an ambient air temperature of 30°C and an air humidity ratio of 17.5 g/kg. This represents a typical outdoor climate of Singapore's summer period. The measured local air speeds are in the range of 0.4 to 1.0 m/s (Figure 1). The results showed that for the given parameters the environment is comfortable (none of the occupants wanted to change clothing nor to change air speed). The survey provides an additional confirmation that the proposed design parameters *SET* and *PMV_{eas}* can be used for comfort evaluation in the tropics. Mentioned work on adaptive comfort models underlines this conclusion [4].

Occupancy
23 pupils
1 teacher

Room geometry
Area: 80 m²
Height: 3.5 m

Doors
operable, on two sides of the room

Windows
opposite on two sides of the room

Six ceiling fans

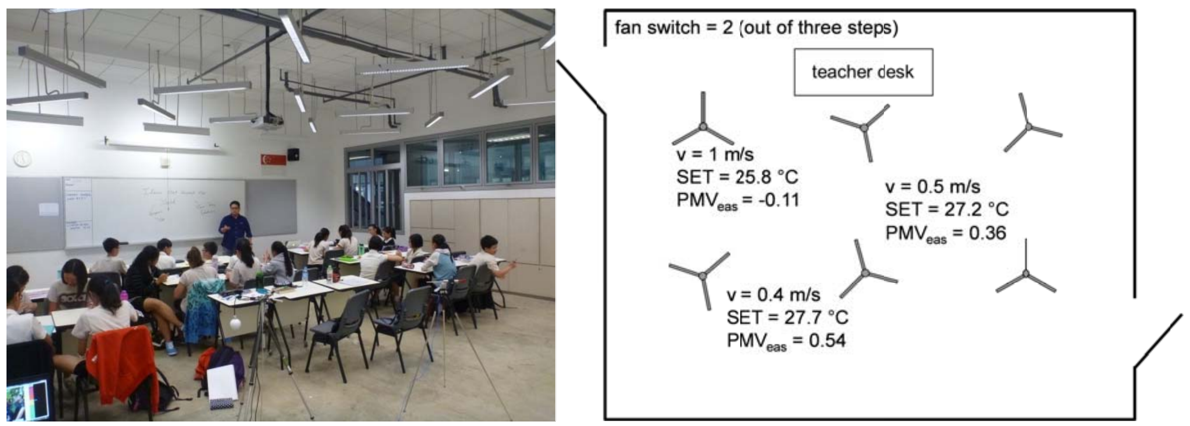

Figure 1 left: classroom at SOTA; right: local air speed and comfort measurements, top view plan of the classroom [6].

Compared to Singapore, Dhaka's summer climate differs significantly in terms of humidity ratio and ambient air temperature (Figure 2).

As a consequence, the BRAC University comfort design could rely on natural ventilation for the winter period, but not for the hot and humid summer time.

Thus, based on the original design concept of the SOTA classrooms energy efficient comfort design strategies for a typical classroom of BRAC University have been compared, analyzing the difference between a conventional fully air conditioned and a hybrid system concept for the Dhaka summer period.

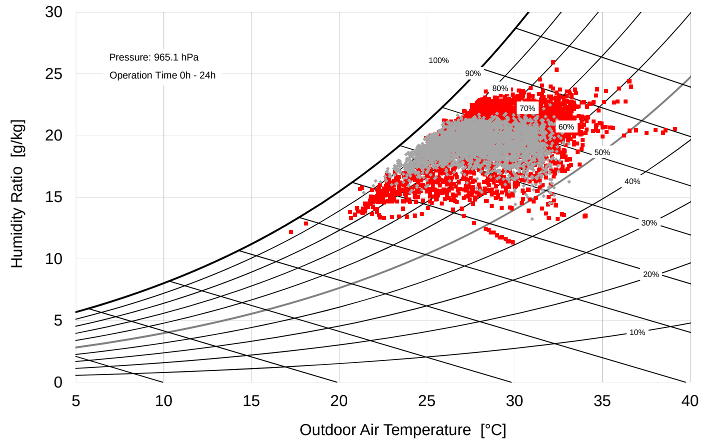

Figure 2 Psychrometric chart with IWEC Singapore (grey) and SWERA Dhaka (red) summer climate data

IMPLEMENTED BUILDING SIMULATION METHOD

All environmental parameters (room geometry, internal and external loads, occupancy, buildings physics, ventilation, cooling power, etc.) are modelled with the dynamical thermal simulation program TRNSYS 3D on an hourly base. In a second step the thermal comfort is modelled based on the calculated environmental parameters and the control strategy of the fans using the *Engineering Equation Solver (EES)* where the codes for SET and PMV_{eas} have been implemented according to the ASHRAE Standard 55-2013.

The simulation model

The thermal simulation work was carried out for a typical classroom model of BRAC University in Dhaka with dimensions 9.0*9.0*3.1 m³. The east and west façades are 30% glazed, semi-outdoor hallways affiliate on the outside. The hallways are naturally shaded by façade plants. For a typical university schedule, the classroom's operation time includes weekdays from 07:00 to 17:00, fully occupied by 40 students. Sedentary activity with 70 W sensible and 65 g/h (40 W) latent load per student as well as adaptive clothing from 0.5 to 1 clo were assumed. In Table 1 the major characteristics of the classroom model are summarized.

Table 1. Simulation settings for the classroom model used in TRNSYS 17 3D

Climate, Shading & Geometry		Time Settings & Occupants		Internal Loads & Air Supply		
Climate Data	SWERA Dhaka	Time	May - Oct	Occupants	110	W/Pers
Shading West/East	External	Operation Day	07:00 - 17:00	Electrical Loads	5	W/m²
Classroom Area	81 m²	Total Operation Hours	1320 h	Artificial Light	10.5	W/m²
Classroom Volume	251 m³	Occupants Number	40	Air Supply	30	m³/Pers

Conventional comfort design with full air conditioning and fan coil cooling

In the tropics, the typical climate concept for offices and public buildings is closed façades combined with full air conditioning. So for the conventional case, a climate concept with conditioned supply air and heat recovery from the returned air combined with fan coil cooling was chosen (Figure 3). Aiming at 26°C operative temperature and 12 g/kg humidity ratio, this system fulfills the conventional "static" PMV comfort standard. For evaluation the following design assumptions are made: Fresh air supply is set to 30 m³/h*pers in order to achieve good air quality for an university environment. Fresh air is

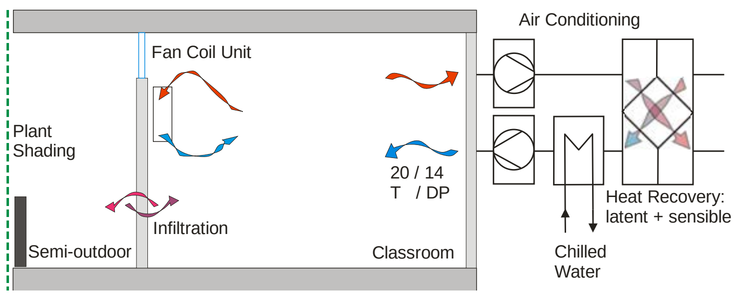

Figure 3 Conventional comfort design with full air conditioning and fan coil cooling

supplied with 20°C and a dew point temperature of 14°C (10 g/kg), the latent and sensible heat recovery is 75%. The fan coil unit is designed to cool the room air to maximum 26°C operative temperature and to keep room air humidity ratio below 12 g/kg. Infiltration is set to 0.2/h. In this system the air conditioning is introducing fresh air, cooling, dehumidification and air circulation (to be distinguished from the air movement in the hybrid system: see next sub-chapter).

Hybrid system comfort design, decoupling cooling from air movement, with tempered air and elevated air speed

For the hybrid system comfort concept fresh air is supplied with also 30 m³/h*pers to the room. The supply air is tempered, meaning cooled to 20°C (resp. 22°C) air temperature and dew point (equal to 14.7 resp. 16.7 g/kg) only. The supplied air is pressurizing the room and spilling over to the hallways, which minimizes infiltration (Figure 4). The condensate from the decentralized supply air units is used for irrigation of the façade plants.

To establish constant comfort, six ceiling fans with controlled air speed are used in addition. Air velocity is automatically elevated in two steps from 0 to 0.7 to 1.2 m/s, if perceived comfort exceeds 0.5 PMV_{eas}. This is set to be in line with recommended limits for air speed of sedentary work (0.7 m/s) and maximal air speed under occupant control (1.2 m/s) according to ASHRAE Standard 55.

For further comparison a design without any mechanical ventilation but natural window ventilation (air change rates, driven by thermal boundary conditions, range from min. 4.8/h to about 10/h) and elevated air speed with ceiling fans has been compared (see next chapter).

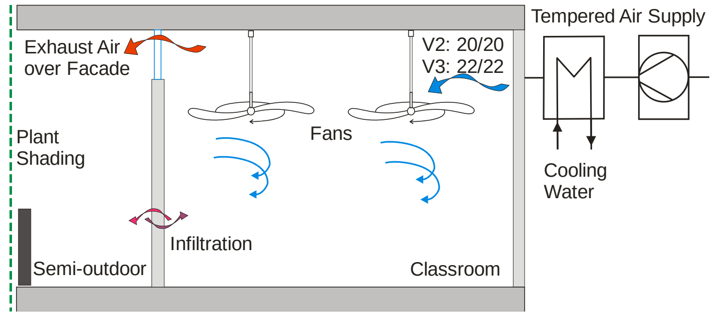

Figure 4 Comfort design with tempered air and elevated air speed

RESULTS AND DISCUSSIONS

In Table 2 the four variants of different comfort designs are compared. The first variant V1 stands for the conventional comfort concept of full air conditioning and fan coil cooling. The variants V2 and V3 are based on the comfort design of tempered air and use of fan. V4 represents the fully natural ventilated design with no air tempering but use of fans.

Table 2.Variants of comfort design for a typical classroom

Variant	Ceiling Fan	Fan Coil Unit	Mechanical Ventilation T_{supply} [°C]	Mechanical Ventilation $T_{dewpoint}$ [°C]	Heat recovery [%]
V1	No	Yes	20	14	75
V2	Yes	No	20	20	-
V3	Yes	No	22	22	-
V4	Yes	No	-	-	-

All four variants have been evaluated on the same basis with PMV_{eas} for the purpose of comparing the achieved comfort. Figures 5 and 6 show that for V1, V2 and V3 the achieved PMV_{eas} is in the range of 0.2 to 0.5. Thus, those variants provide excellent comfort. In contrast, V4 provokes uncomfortably warm conditions, even though fans are at high air speed of 1.2 m/s (Figure 8). Its PMV_{eas} increases up to typically 2, in maximum to 3. Thus, V4 is not discussed any further.

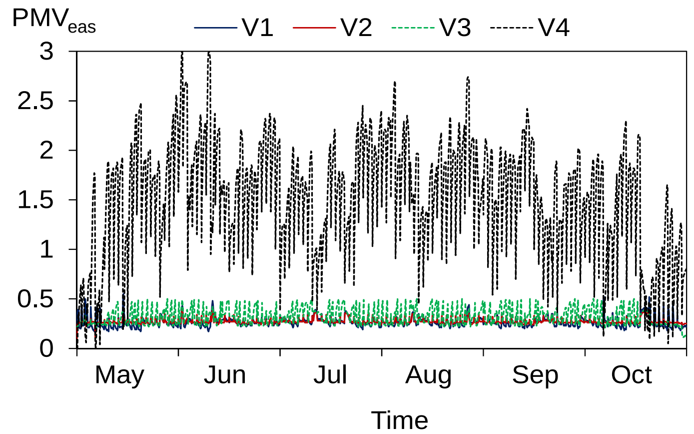

Figure 5 PMV_{eas} curves of comfort design variants over Dhaka's summer period

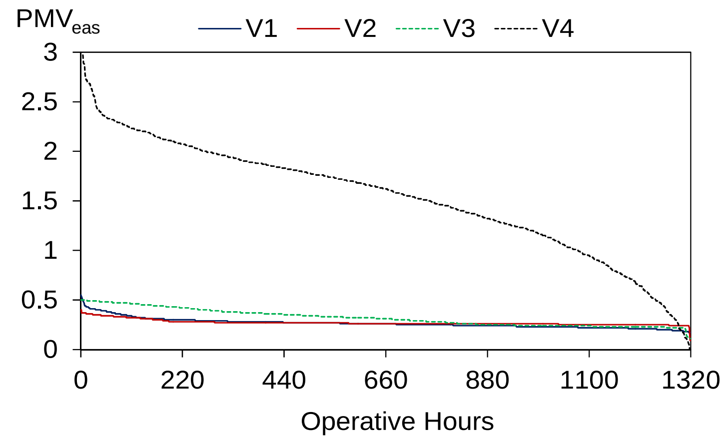

Figure 6 Sorted PMV_{eas} curves of comfort design variants over Dhaka's summer period

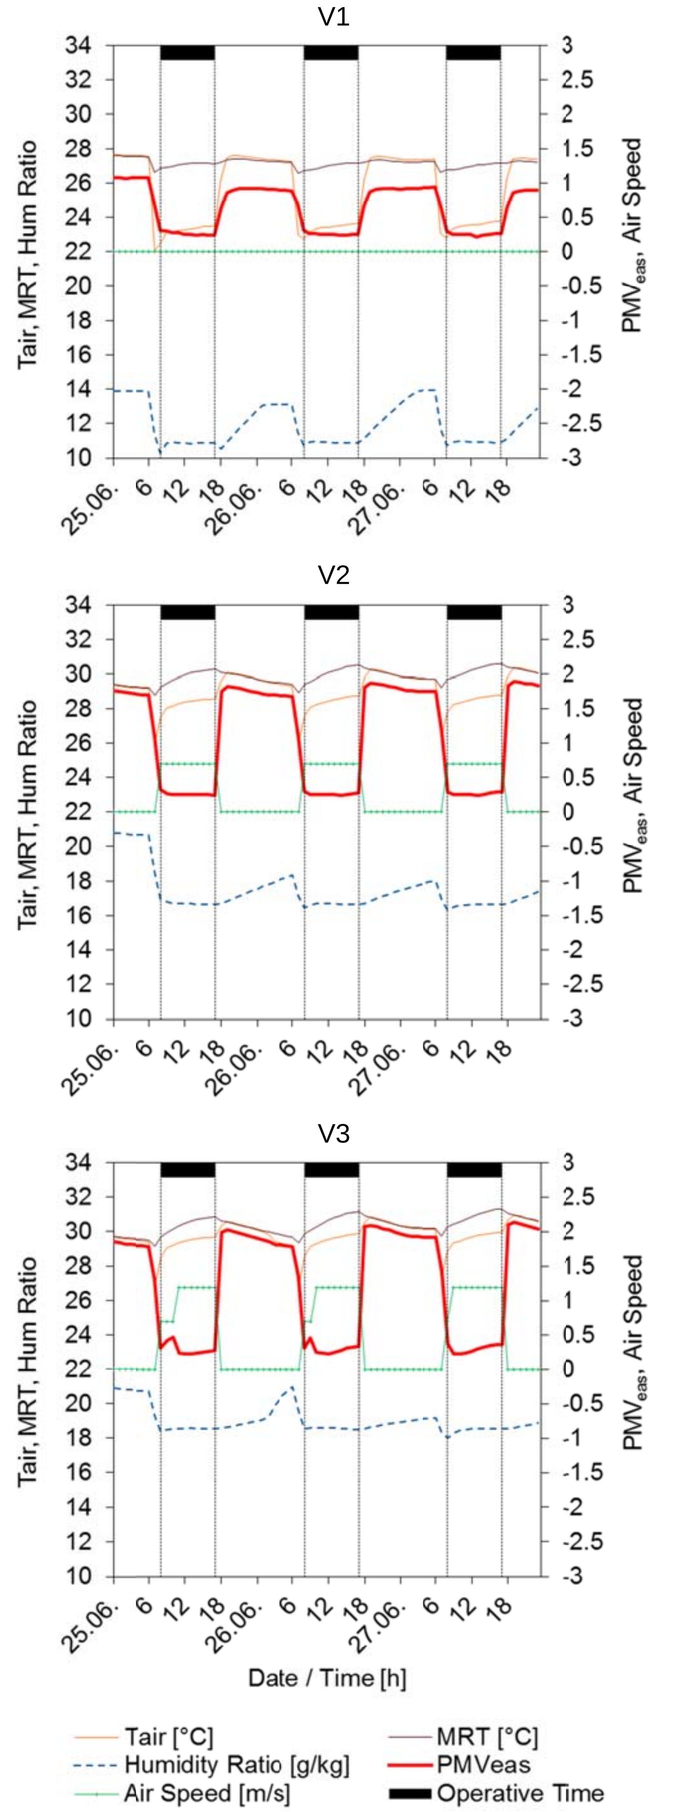

Figure 7 Design day chart showing the achieved PMV_{eas} and its major parameters for the compared variants [7]

Figure 7 on the left gives a detailed comparison of the parameters' interaction for variant V1, V2 and V3. Three design days in June were chosen to represent a typical summer situation in Dhaka. The results from the thermal simulation were used as input parameters for comfort calculation [7]. T_{air}, MRT and humidity ratio are plotted on the left ordinate. Determined fan step as well as resulting PMV_{eas} are shown on the right scale. Black plotted bars at the diagram's top indicate the occupants' operative time.

V1 leads to average values for T_{air} with 23.5°C and MRT with 27°C, and to a reduced average humidity ratio of 11 g/kg (Figure 7, diagram at the top).

In contrast, the hybrid variants allow higher T_{air} and MRT values between 28°C and 31°C and higher humidity ratio of 16 to 18 g/kg. The impact of high temperatures and humidities is compensated by elevated air speed causing comparable PMV_{eas} values in the range of 0.2 to 0.4 during occupation.

The comparison of V2 and V3 shows that a fan speed of maximal 0.7 m/s is sufficient for V2, whereas the slightly warmer and more humid environment in V3 requires 1.2 m/s for most of the operative time in order to keep the PMV_{eas} at the same range (Figure 7, middle and bottom diagram). To provide the same comfort in all variants with fan, the six ceiling fans run constantly during the 1320 h of occupation (Figure 8).

V2 establishes good thermal comfort while constantly using the lower fan step of 0.7 m/s at all 1320 hours of operative time. With V3 a higher average air speeds is necessary due to the reason mentioned above. Almost one third of operative time the higher fan step of 1.2 m/s is required. If this would be acceptable to the users the energy savings would be about - 42% (Figure 9).

But as ASHRAE 55 recommends limiting air speed for sedentary activity in the occupied zone, V2 with 0.7 m/s air speed is the preferred variant even though the energy savings are less with - 25%.

The comparison of the variants' energy demand (Figure 9) gives evidence that substantially less mechanized concepts can achieve significant energy savings even though no heat (cold) recovery is installed.

As room air temperature and humidities are higher compared to conventional systems additional sensible and latent heat recovery would be less effective. For V2 cooling energy could be reduced e.g. from 66 to 45 kWh/m²a, but a full sensible and latent hreat recovery system (75%) would be required.

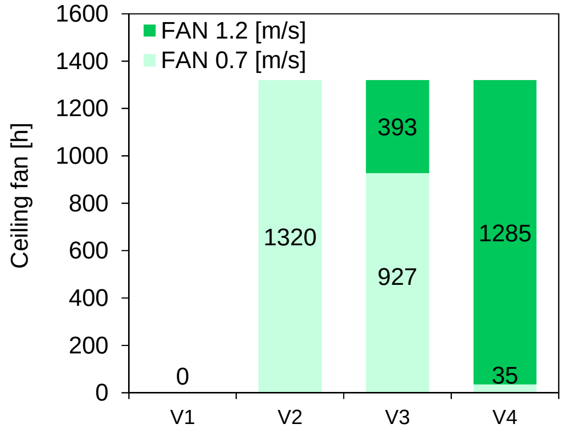

Figure 8 Running hours of fans of each variant, accumulating to 1320 h of total operative time

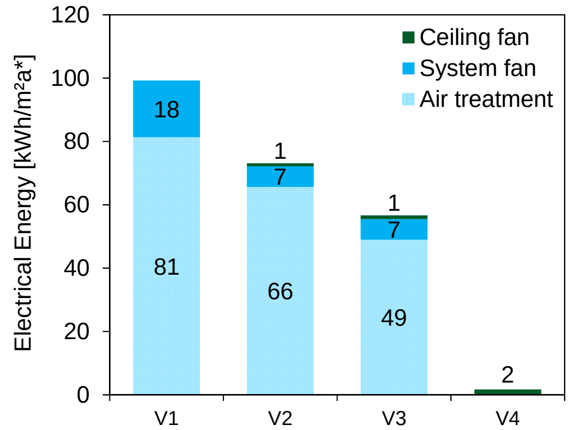

Figure 9 Electrical energy demand of each variant for ventilation, cooling and dehumidification (COP 3)

CONCLUSIONS

The paper's purpose is to investigate whether a hybrid system comfort design can lead to significant energy savings while providing equal comfort compared to the conventional concept of full air conditioning and fan coil cooling.

Methodology, implementation in building simulation, and analysis of thermal concepts for a typical university classroom in Dhaka, Bangladesh, have been carried out. The implemented method based on ASHRAE's SET-PMV comfort evaluation for elevated air speed proved to be a powerful tool to explain thermal comfort achieved with 100% fresh air supply of tempered air and the use of ceiling fans as typically installed.

Based on the results, a hybrid system comfort concept with dedicated fresh air supply is proposed which provides good fresh air quality with 30 m³/h*pers and excellent thermal comfort. A simple decentral mechanical system is proposed to supply the fresh air at 20°C temperatures and dew point. In addition, ceiling fans provide acceptable air movement during operative time. Compared to the conventional concept of conditioned air with full heat recovery aiming on 26 °C operative temperature and 12 g/kg humidity ratio, energy savings are about 25%.

The supply air systems can be installed decentral and operated per room in case of occupation only. Typical installations for mechanical rooms with central air conditioning systems, heat recovery, insulated supply and return air ducts in false ceilings, vertical shafts etc. are not required. The substantially lighter hybrid system will have lower investment costs of the system itself as well as for the building as less space is used for the air handling systems and will allow a more simplified building envelope design and thermal zoning of the university building.

It is to be noted that achieved comfort of the systems analysed is comparable, while their influencing environmental parameters configure in two complete different ways: the hybrid system variant provides comfort with high operative temperatures and high humidity compensated by elevated air speed, whereas systems with full air conditioning and fan coil cooling run on low operative temperatures and low humidity without elevated air movement.

While similar built examples of hybrid systems exist, the paper's outcome fills the gap of a missing methodology to assess hybrid comfort designs in tropical climates. The method proved to be useful for these design evaluations.

LEARNING ENERGY SYSTEMS: An holistic approach to low energy behaviour in schools

Kate Carter, PhD
University of Edinburgh
k.carter@ed.ac.uk

ABSTRACT

Existing buildings are aligned with substantial energy use. Energy modelling is failing to produce an accurate prediction of the energy needed to operate buildings, particularly in the education sector. Schools and higher education estates often use 50% more electrical energy than the design models show. Much of this is associated with what is termed 'unregulated' energy, in other words, energy associated with unpredicted use of the building.

Working with sets of energy data, school pupils, teachers and building managers were involved in an action research project around the theme of lighting energy. This led to a reduction in energy use by lighting of 15%. Lighting control systems and education and awareness of energy use both contributed to this reduction. The study considers the benefits in financial terms. The relatively small gains offer significant potential over the lifespan of a school building. The wider benefit is in the involvement of building users in the management of their energy use.

INTRODUCTION

Understanding the way people use energy is seen as the key to improving energy performance in buildings. This paper presents a pilot study examining an interactive response by school children to the management of lighting in their school. It is part of a wider research project exploring the integration of the 'human' into the energy management of school buildings. The pilot study combined the use of energy data, and lux level measurement with action research in the school building.

It is estimated that lighting for buildings consumes 19% of global electricity generation (Grinfeld and Grinfeld 2009). Improved energy efficiency of lighting has resulted in an overall reduction in this load. UCD-OPET (1994) identifies 12% of energy use for lighting in typical UK schools in the 1990s. This had reduced to 8% in 2012 (Carbon Trust, 2012) due to improved lighting efficiency, however this equates to 20% of the energy costs of the building. This is why it is so important to reduce the amount of energy we use in for lighting (Ryckaert, Lootens, Geldof, & Hanselaer, 2010). Artificial lighting is dependent on electricity and has the highest CO_2 emission factor of energy sources (compared to gas oil and coal) at 0.422 $kgCO_2/kWh$ which further emphasises the need for reducing the energy used for illuminating our buildings (Lee & Guerin, 2010). As well as the cost to the environment, is the cost to society in energy bills. Reducing the energy use of public buildings will reduce the financial burden on local government (Di Stefano 2000).

The amount of energy used for lighting in public buildings is affected by two primary factors: the design of lighting system; and the users of the building and their attitude towards the energy. This study focuses on a primary school building in Scotland, and encompasses an overview of the types of lighting control currently used in existing school buildings. By involving building occupants, the study examines how these lighting controls can be better used and managed by building occupants to reduce their consumption of electricity, and if modification of building users' behaviour and attitudes towards energy use can reduce the overall energy consumption of the building.

LIGHTING CONTROL

Well designed and controlled lighting systems can reduce the energy use of artificial lighting by up to 40% (Grinfeld and Grinfeld 2009). For optimum energy efficiency a lighting control system must be designed so that it generates the required lux levels, delivering lighting using the least amount of energy (Karlen, Benya, & Spangler, 2012). Control systems have become more sophisticated and range from individual control, to highly sensitive computer operated building systems. This range of systems is found in the school being used for this study.

Local manual switching usually comes in the form of wall switches that can be controlled by building users with on/off or dimming switches (Simpson 2003). Relying on manual switching can lead to a high amount of wasted energy if occupants do not control them efficiently (Rawlinson 2008). Local manual switching is used in the classrooms in the school being studied. Centralised switching can be operated automatically at certain times in the day relating to the operating hours of the building (Wall and Everest 2003). Manual switching is still possible with this system to override automatic settings. If the system is well designed, studies show that few occupants will use the manual override (Grinfeld and Grinfeld 2009). This type of control is used in the corridors and assembly halls of the school but the manual override function is kept locked and can only be operated by the janitors.

Occupancy sensors are used to automatically: turn lights on when a space is occupied; keep lights on while the space is occupied; and turn off the lights once the space is no longer in use (Simpson 2003). The lights will be automatically turned off again after a definable period of inactivity. A Post Occupancy Evaluation (POE) carried out by Buro Happold (engineering consultancy company) on five schools built in the UK between 2002-2005 revealed that the use of PIR sensors saved 30-40% compared to manual switching (Pegg 2009). This study found that general circulation lighting was the worst managed, especially in areas such as atriums. This is due to the space not being 'owned' by anyone, therefore responsibility for the operation ofthese lights needs to be addressed (Pegg 2009). It is very important for building designers to think about maximising the use of daylighting when designing a building (Loe 2009). Photoelectric lighting controls (daylight linking) can either be an on-off system or a dimming system (Grinfeld and Grinfeld 2009). This type of control is present in the classrooms of the school.

Programme Logic Controllers (PLC) are centralised lighting management systems that control a whole building e.g. a school (Grinfeld and Grinfeld 2009). They consist of a computer based system that can control a combination of presence detection, daylight linking, timed and manually operated lighting systems to provide optimum control, tailored to a specific building and its users needs (Rawlinson 2008). PLCs in conjunction with a mixed manual and automatic control system will use energy most efficiently as long as they are designed to be user friendly (Loe 2009). They are also used in lumen maintenance as a new lighting system may be over specified, therefore it can be dimmed initially and power can be increased over time as the lamps lose light (Grinfeld and Grinfeld 2009) to prolong their life. The school studied has a computerised PLC system (Philips Light Manager) which allows alterations to be made to lights in the school that are controlled by automated PIR, daylight linking and timed systems.

BUILDING OCCUPANT BEHAVIOUR

The behaviour of building users can have a large effect on the amount of energy that the building consumes (Hori, Kondo, Nogata, & Ben, 2013; Masoso & Grobler, 2010). Newborough and Probert (1994) take the strong view that a lack of awareness in how energy is consumed is illiterate and apathetic. AI-Mumin *et al.*(2003) makes a statement that concurs with these views saying that 'energy-unconscious' behaviour of building occupants can lead to an excess in energy consumption. Zografakis (2008) holds the view that young people need to be properly educated on energy saving matters so that our future energy use will bereduced and that the way to do this is the education of students throughout their school life to instil an 'energy saving culture' (Faiers, Cook, & Neame, 2007; Zografakis, Menegaki, & Tsagarakis, 2008), thus creating a more energy literate society (Newborough & Probert, 1994).

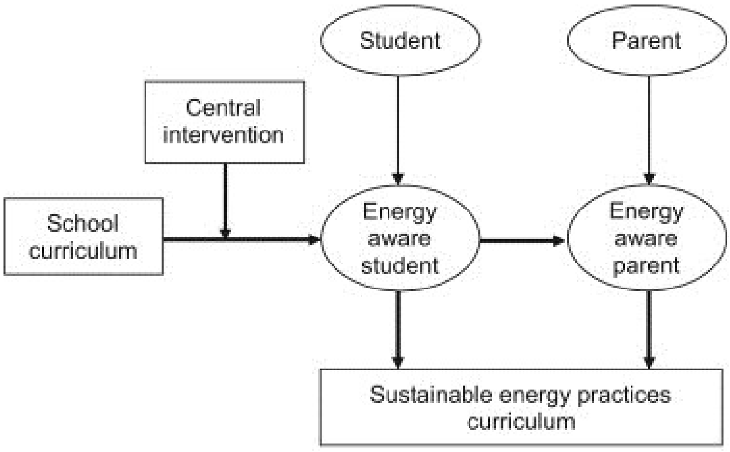

Figure 1: The effects of energy related education in society (Zografakis et al. 2008)

Figure 1 demonstrates how energy education leads to a higher understanding of the need to save energy and encouraging energy efficient behaviour. Although buildings consume the most energy during the day, often the most energy is wasted when the building is unoccupied. This is due to users leaving lights on overnight when they are not needed (Masoso & Grobler, 2010). There is a great need for building occupants to be more energy aware and learn to switch off lights and appliances when they are not being used, to reduce energy wastage (Al-Mumin, Khattab, & Sridhar, 2003; Masoso & Grobler, 2010).

The attitudes and behaviour of building occupants can undermine energy efficient building systems and technology and the two must work in harmony for significant reductions in energy use to be realized (Hori et al., 2013; Masoso & Grobler, 2010). At the same time building designers must gain accurate knowledge of how a building will be used to tailor the design to the users to achieve maximum energy efficiency (Carbon Trust, 2012).

The advantages of behavioural change through education are numerous (Dias, Mattos, & Balestieri, 2004). The potential energy saving could be more than is possible with just energy efficient equipment and systems. It is relatively very cheap and can be applied to any building new or existing (Masoso & Grobler, 2010). They make the argument that to improve energy efficiency; we should concentrate more on improving occupant behaviour and attitudes through education in energy awareness, rather than solely focusing on energy efficient technologies. Many lighting systems in public buildings, such as schools are very complicated. Even with a well designed system, for a building to reach its maximum energy efficiency it is necessary to have energy aware building users (Winterbottom & Wilkins, 2009).

ACTION RESEARCH IN LIGHTING USE

The study involved a group of school children in an action research project associated with lighting in their school. Involving school children in the study helps us see energy use from the eyes of the child. This user group offers a perspective that is often omitted from building management strategies in schools. The opportunity to engage children in the active management of energy use in their schools presents a novel response to the need to reduce energy, and fundamentally, it increases the pool of participants with responsibility for energy use.

Methodology

The research was designed to test two propositions: the behavior and attitudes of staff and pupils at the school will change in response to learning about how lighting uses energy; and that involving building users in the control of the lighting system will lead to a reduction in energy use. Recognition that this was about problem solving, led to an action research approach. This involves interaction to improve the situation, and this pro-active approach offered efficient empirical data collection, vital to the evaluation of the study (Costello, 2011).

The first visit to the school, led by the Facilities Manager, involved quantitative data collection on the lighting system of the school. This included lamps, luminaries and control systems to allow assessment of the energy efficiency of the current lighting system and to see if the hardware and technology could be improved. This was followed by the first phase of the 'lighting use survey'. Another visit to the school, led by the deputy head teacher, enabled qualitative data to be gathered relating to the energy saving attitudes and practices of the school, and an 'energy awareness presentation' to inform the whole school about the lighting study. This was followed by the second phase of the 'lighting use survey'. Figure 2 illustrates the action research process.

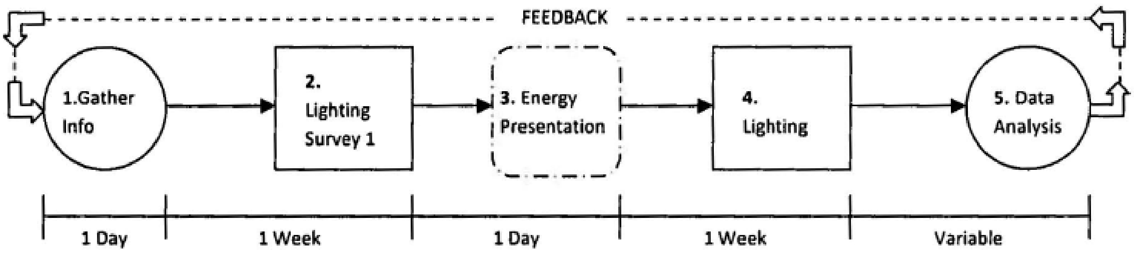

Figure 2: Action Research Process

The action research involved pupil members of the Eco-Committee undertaking the 'lighting use survey' over two separate weeks. Four areas of the school were chosen for the study to capture a range of lighting systems: a general classroom; a science room; the dinner hall; and a shared seating/circulation area. The study was carried out before and after the 'energy awareness presentation' to enable the impact of this session on energy behavior to be gauged.The survey was set up to record three sets of quantitative data:

1. If the lights were on or off at hourly intervals throughout the school day from 9am until 4pm Monday to Friday.
2. If the room was in use during these times.
3. The lux level. (meter placed on table in centre of room, for every reading)

Data from the first phase was used in the 'energy awareness presentation', delivered at a school assembly to all pupils and staff at the school. This provided pupils with information about energy sources both renewable and non-renewable and how we consume this energy. The presentation was designed for primary school children in accordance with advice in the paper '*EnergyEducation*' by Kandpal & Garg, (1999). Repeating the 'lighting use survey' following the presentation meant that changes in awareness and attitudes to lighting use could be evaluated in terms of actual decreases in lighting use.

Action Research results

Two sets of quantitative data were produced. The first week shows normal lighting usage in the selected areas of the school. The second week demonstrates lighting use after problem solving action in the form of an educational presentation. This allows simple measurement to determine if the change in behaviour of the occupants could have a significant effect on reducing the energy use of the school from lighting. The four rooms used in the study offer distinct use patterns. The Dinner Hall and Shared Area are used occasionally by large numbers of pupils and are not associated with any particular class group. The Classroom is occupied by the same group of children for the majority of the school week. The Science Room is used occasionally for specific class activities by small groups of pupils led by a teacher.

The action research led to a reduction in energy use from lighting in all areas apart from the Dinner Hall (Figure 3). The graphs show the number of hours that the lights were on and the number of hours that each space was occupied. The significant reduction in energy use is seen in the rooms that are occupied by defined groups (classes). The two large areas with occasional use showed small improvements in redundant use of lighting, and demonstrate the difficulty faced in managing energy consumption in spaces that are not 'owned' by their occupiers.

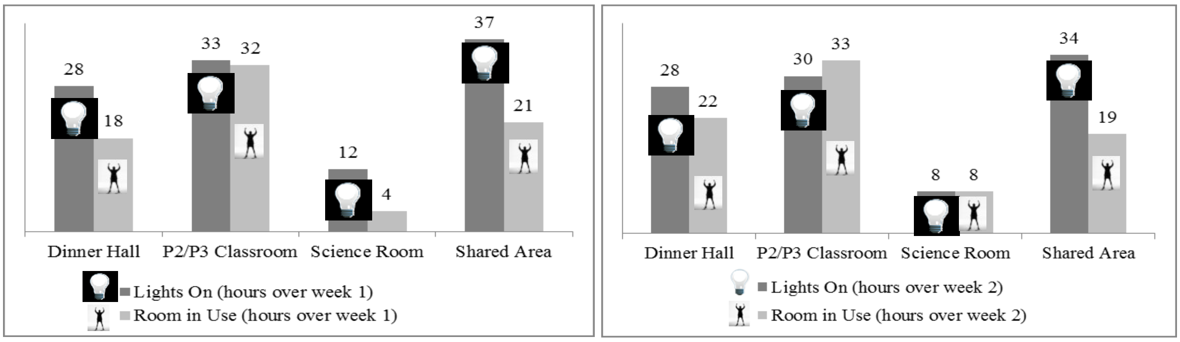

Figure 3: (a) Light and Room Use in Phase 1 (b) Light and Room Use in Phase 2 (numbers represent hours that light is on or room is occupied)

Room Area analysis

The dining area is controlled by a key operated switch box that is kept by the janitors. This meant the energy use could not be directly controlled by the room users. This seems to be linked to energy waste (lighting on in an empty room) at 36% in the first week's study. Redundant light use decreased by 15%. The lighting use was identical over the two weeks but the physical use of the room increased corresponding to an increase in the lighting efficiency (lighting on in a room that is being used) from 64% to 79%, however this cannot be correlated with energy saving behaviour. The lux level was above the recommended 500llux for dining halls in CIBSE (2002) at an average of 770lux during the both weeks of the study. Therefore daylight linking would provide a direct reduction in energy use.

The control system in the classroom is quite advanced as there are three sets of lights. The sets of lights at the window and the corridor side of the classroom are controlled by two daylight sensors at either side of the room. If there is the required lux level of 500lux (CIBSE) then the lights will switch off in that area to save energy. The main on/off switch is located in the classroom and is therefore user controlled. The energy use in this room was very good in the first week's study, 97% of the light was being used and only 3% was being wasted. However in the second week an improvement was made as there was no wastage of light and the room was in use for three hours when the lights were turned off, as daylight would supply the required lux level. The room also used 3 hours less energy in the second week with the similar amount of use. The lighting system is quite advanced. The luminaries are energy saving models with high frequency ballast. However the control system could be improved by the daylight linked lights being dimmed rather than turned completely off. This will save more energy, extend the life of the lamps and be less distracting to room users (Roisin et al. 2008, Li et al. 2010). The average lux level over the two weeks was 510 lux which is very close to the recommended 500lux for classrooms.

The control system in the science classroom is very similar to the P2/3 Classroom as there are three sets of light. The main lighting switch is user controlled. The lighting wastage from this area in the first week was a relatively high at 67%. In the second week 4 hours less lighting the lights were only used when the room was occupied. As with the P2/3 classroom, the lighting system in the science room is quite advanced. The control system could be improved by the daylight linked lights with a dimming setting as recommended for the P2/3 classroom. The average lux level over the two weeks was 415 lux which is slightly below the recommended 500 lux for classrooms.

The lights in the shared area are controlled on a simple series circuit. These lights are on the same automatic control as corridors, and will be 'held on' as long as lights are on in a room in that area. The overall energy saving in this area over the week was 3 hours but the energy wastage stayed at a high 43%. The lighting system is quite advanced. The luminaries are energy saving models with high frequency ballast. However the control system could be improved by the daylight linked lights as the shared area is located beside two large windows. The average lux level over the two weeks was 554 lux which is much higher than the recommended 200 lux for shared circulation space. This means that the lights could be dimmed to save energy (Li et al. 2009).

Overall in week 1 of the study the four rooms in the study had lights on and the room not occupied for 32% of the time. The use of lighting when not required (i.e. day lighting adequate or room not occupied) reduced by 15% in week 2 of the study.

Cost Analysis

Table 1 shows the savings per week which were calculated by multiplying the power load for the room in watts (electricity use when lights are on) by the by the number of hours the lights were used. This gives an amount of power used in watts which is then divided by 1000 to give an amount in kilowatts. This is a necessary step as a buildings electricity use is measured in kilowatt hours (kWh). The amount of kWh is then multiplied by the unit rate for the school which was at £0.0671 at the time of the study.

Area	Saving from energy education/ week	Saving from dimming lights/week (-20%)	Estimated saving from daylight linking (-15%)	Total combined saving/week
Dining Hall	£0.00	£0.55	£0.41	£0.96
P2/3 Classroom	£0.21	N/A	N/A	£0.21
Science Room	£0.08	N/A	N/A	£0.08
Shared Area	£0.10	£0.22	£0.17	£0.49
Actual Savings	£0.39	£0.77	£0.58	£1.74
Total across school/week	£19.45	£15.40	£11.55	£46.39
Total across school/year	£719.49	£569.63	£427.22	£1,716.34

Table 1: Potential cost savings from lighting efficiencies

The lighting cost was then multiplied by the number of similar rooms or spaces to give a total saving across the whole school campus. This figure was then multiplied by the number of operational school weeks in the year to generate an estimated figure of yearly energy savings. Firstly the estimated yearly energy saving from regular energy awareness presentations is £719.49. This is therefore an effective energy saving measure with a low implementation cost. The lighting system is controlled by Philips Light Manager system which could dim the lights in the appropriate rooms via the computer control system. The lighting savings from dimming the lighting by 20% came in at a lower yearly saving of £569.63 which is possible with the existing lighting infrastructure and is therefore an affordable and feasible energy saving measure. Two out of the four rooms studied could benefit from daylight linking systems as they are located near windows. Although this indicates a decent saving of £427.22, this does not take into account the cost of installation. Therefore with only a small expenditure for energy awareness presentations combined with dimming lights, there is a potential saving of over £1,200 per year to be made. On top of this, if the daylight linking systems were found to be financially then even more money could be saved on lighting. The cost analysis offers realistic scenarios with commonly used equipment and control systems found in many modern buildings. The installation has a sophistication that offers the ability to respond to the lived experience and feedback on the people using the buildings with small cost implications.

CONCLUSION

Active involvement of building users in the management of buildings is shown to lead to better peforming buildings (Bordass & Leaman, 2005). This study has shown engagement with quantitative monitoring, and qualitative education, that direct gains can be made in energy reduction. The focus on lighting provided a tangible and visible energy stream that was measureable and controllable by the project participants. Involvement of school children in this action research is important to embrace the idea of energy communities and their ability to manage energy demand (Fazeli, Christopher, Johnson, Gillott, & Sumner, 2011). The reduction in lighting use experienced in this study, seems to be linked to feedback data on lighting use, combined with an educational presentation on energy.

These results show that there is a large scope for energy saving through different aspects of lighting control. This can be done by either changing how the lighting operates using the PLC or changing how the lighting is operated by changing the behaviour and attitudes of the building occupants. It also highlights that there is little or no energy savings to be made by upgrading lamps and ballasts at the moment as the school has very up to date technology.

The study provides useful insights into the effectiveness of including people in the management of complex energy systems. Modern energy infrastructure is increasingly relying on complex building management systems (BMS) to monitor and control systems. In the study building a sophisticated lighting control system is installed. The way in which it has been set up does not relate to the way in which the building is being used. The involvement of building occupants in their environment offers potential for improving the way that complex systems can operate and respond to the lived experience of these people.

This study is part of a larger project, Learning Energy Systems at the University of Edinburgh, currently exploring methods to better integrate building occupants into the management of energy in their school buildings. This study demonstrates that with small interventions, significant energy reduction is possible over the life span of a building by addressing user behavior. In this case 15% reduction in lighting use was achieved with minimal intervention or alteration to the lighting control system. This potential this offers to a wider range of energy use beyond lighting in school buildings is considerable, and this provides interesting context for further work in this area.

ABSTRACT

This paper describes the design of a system to monitor high performance building strategies and to visualize performance. The implementation of the system at a 640 m2 educational center in San Francisco is discussed, with reference to specific renewable energy systems and sustainable building strategies. A variety of off-the-shelf as well as custom sensors was specified in order to monitor these strategies specifically. Since the center uses the data for education and research, the approach to data visualization required addressing the needs of a wide variety of users. A dashboard was designed so that occupants, managers and the public could understand how the building was performing in real time, as well as at different time scales. Rather than simply graphing data, the dashboard places data in meaningful context. In addition, advanced visualization techniques are used as a complement to the dashboard to gain further insight into patterns and tendencies in building behavior.

INTRODUCTION

Building energy and environmental monitoring has many potential benefits, including helping to maintain high energy performance, providing feedback to design teams, and tracking energy use that can be controlled by occupants (NBI 2009). As low-energy design increasingly relies upon multiple strategies to provide a visually and thermally comfortable interior environment, it is critical that variables relevant to that performance are monitored. Furthermore, this understanding may be realized only if data visualizations reveal relationships that are indicative of performance, translating data into knowledge (Marini et al 2011). This paper presents a monitoring and dashboard system we designed to meet this goal.

PROJECT BACKGROUND

This monitoring project came about during the design of temporary relocation of the Crissy Field Center (CFC), a National Park Service organization focused on education and outreach. Their programs consist largely of collaborations with nearby schools to provide environmental education to supplement elementary through high school science curricula. CFC conceived of the relocation project as an opportunity to demonstrate and test a variety of sustainable building strategies. Project Frog was hired to deliver a building containing a number of sustainable features on a short construction schedule, and Loisos + Ubbelohde was an ongoing consultant to Project Frog on energy and comfort issues. The building achieved LEED Platinum certification and consists of the “cafe” and the “center" (see Figure 1). The cafe (about 130 m2) is open to the public and contains seating, counter service, and a food preparation area. Food is prepared off site, so kitchen activities are limited to refrigeration, reheating, and sanitation. The center (about 510 m2) has no public access and consists of two classrooms, a large gathering area, three open office areas, a computer lab, a small kitchen, lavatories, and several other small support spaces.

Sustainable Strategies

While a number of sustainable strategies were integrated, this paper presents selected strategies that are relevant to energy and comfort performance. The building seeks to take advantage of its location adjacent the bay in temperate San Francisco. Although conventional thought would have included air conditioning to address the potential for occasionally significant space loads, the client and project team favored the sustainability benefits of excluding air conditioning. An under floor air distribution (UFAD) system was specified to provide ventilation air and space heating. The team believed that the raised floor construction had the potential to influence space comfort via the surface temperature of the floor as well as via the air. Most spaces have ample access to daylight. Electric lighting is controlled by daylight and occupancy sensors.

A number of renewable technologies were included in the project. Solar energy was harvested for electricity and hot water heating. A 28.35 kW photovoltaic (PV) array sits on the roof and includes micro-inverters to convert DC to AC power at the module. A 9.9 m2 solar thermal collector designed to be the primary supply of hot water for the cafe. Wind energy is harvested using five vertical axis wind turbines. Lastly, a rainwater collection system gathers rainwater from the roof for use in toilets.

MONITORING

The monitoring system includes a variety of hardware components from individual sensors to a cloud-based data management server. Selection of these components related to the needs of the project. Output from renewable systems needed to be monitored, including electricity produced by PVs and wind turbines, heat collected by the solar thermal system, and rainwater used. A weather station including solar radiation, wind speed, and rainfall, was also specified in order to understand available resources. To address envelope and mechanical system performance, energy meters were specified to indicate flows of electrical energy and natural gas, and environmental sensors were specified to monitor comfort conditions. Specific components of comfort were prioritized for a variety of reasons. These included air temperature, radiant temperature, humidity, and carbon dioxide. We identified a variety of sensors to meet these requirements. These included current transformers and electrical meters, gas and water meters, and interior humidity and carbon dioxide sensors. We chose to build custom temperature sensors since these gave us the ability to embed sensors at locations not possible with off-the-shelf products (see Figure 1). In order to collect data from all these sensors, we built a hierarchical system of nodes to systematically convert signals to variables, collate variable measurements within a consistent timestamp, upload data to a server, check for errors, and store data. Wherever possible, we used widely available products and technologies, while resorting to custom solutions where needed.

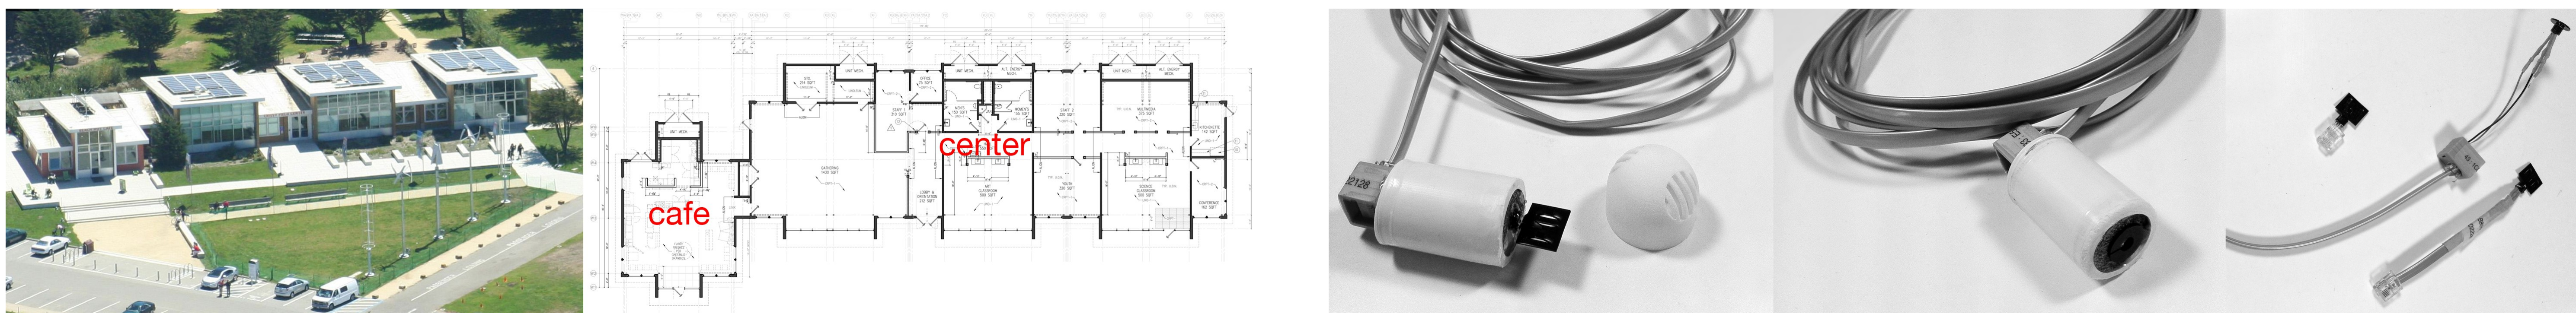

Figure 1 *Aerial view of Crissy Field Center, plan (left); custom sensors for air, wall surface, plenum air, floor surface, and duct temperature (right).*

DASHBOARD

The requirements of the dashboard were born of the educational mission of the client as well as the desire of all team members to make the performance visible. The team imagined a variety of user types, including students at the center, teachers, interested members of the public, facilities managers, administrators, and specialists in high performance buildings. Through an iterative design process, we sought to make data come alive by providing quantitative and qualitative context to data. Several critical features emerged from this process that relate to data representation:

1. Data would be represented at multiple levels of detail, starting with a high-level summary to provide a single assessment of performance and to engage users (see Figure 3).

2. For more detailed time series representations of data, multiple related variables would be shown on a consistent time scale to facilitate comparisons between variables (see Figure 2).

3. Users would have the ability to look at data across different time scales, allowing them to study trends that could occur on different time scales, from a day to a year.

Figure 2 *Dashboard interface showing comparison of several variables on a consistent time scale.*

4. Graphs would be specifically designed for the variables displayed. For example, stacked area graphs show trends in energy end uses (see Figure 2), and line graphs showing temperature relative to a comfort zone (see Figure 4).

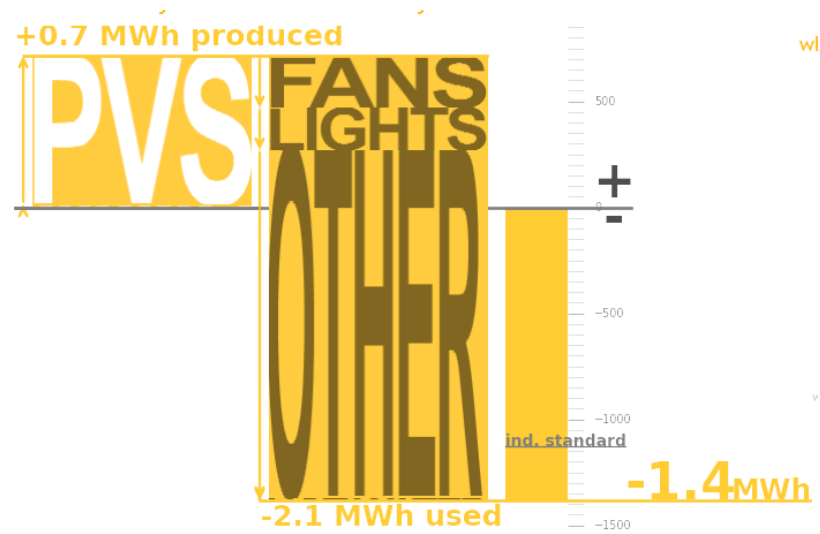

Figure 3 *Summary graph showing net energy performance and end uses.*

The Dashboard in Use

To more fully illustrate how the dashboard is used, we present some observations made and lessons learned from the dashboard in use. We note not only the usefulness but also some limitations of this fixed set of representations. As the dashboard allows users to answer questions, it also leads to more questions that require an additional, deeper and more customizable layer of data visualization for the most advanced user.

An energy summary graph scales text height to emphasize end uses that are more significant (see Figure 3). The graph shown here is typical of multiple timeperiods, with PVs producing so much more energy than the wind turbines that the bar representing the wind turbines is all but invisible (it is located beneath the section labeled "PVS"). Also, we see that "OTHER" accounts for most of the electrical load. Subsequent inquiries have revealed opportunities for optimizing energy use, such as replacing an industrial refrigerator that is lightly used, or working with the IT department so that all computers don't have to remain on all the time just for an infrequent software update.

A series of graphs of related variables comprises detailed view. In Figure 2, we begin to see the relationship between PV production and available solar radiation. We again see that the PVs outproduce wind turbines, but it is not clear if this is a fair comparison of the two technologies. A variation of this view also begins to reveal that more electric lighting energy was used during the more cloudy day, indicating that the building shows a response to the availability of daylight.

Finally, figure 4 shows a view into the thermal performance of the space. Here, it is clear that the floor surface temperature remains more consistent and cooler than the air temperature. With all of these trends, we have learned something about how the building was performing during a particular period in time, but we might also ask more specific questions about how these trends fit into the yearly performance of the building.

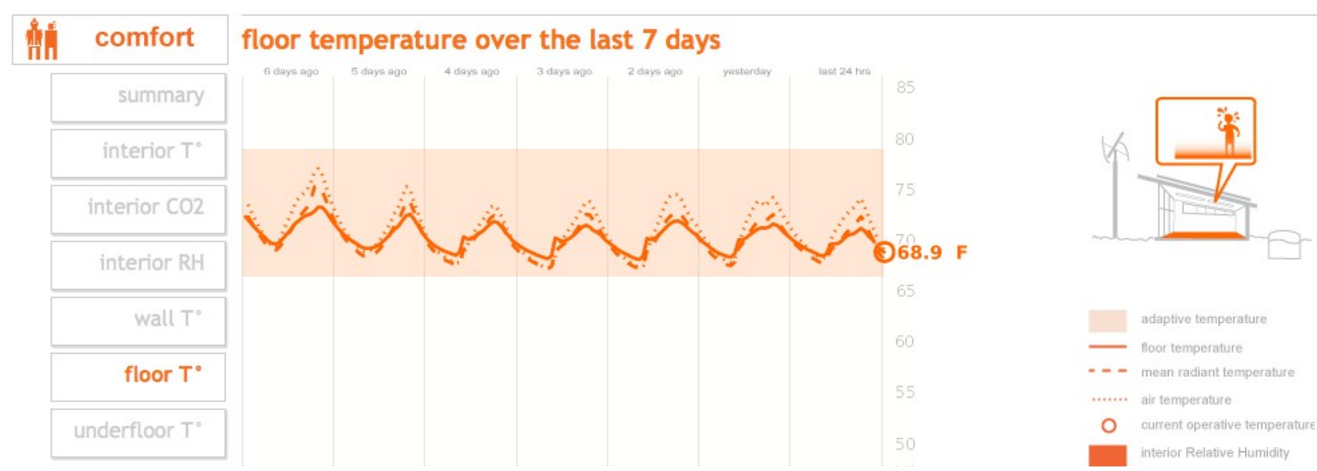

Figure 4 *Detailed temperature trend graph showing comfort zone, air and surface temperatures.*

ADVANCED DATA VISUALIZATION

Advanced dashboard users might ask questions that require a more sophisticated approach to data visualization in order to reveal behaviors that can help answer questions. Since the monitoring system allows for retrieval of data in an organized format, it may be explored using open source tools. The following graphs show examples of such an exploration of the data using the Pandas, Matplotlib and NumPy Python libraries within the iPython Notebook environment.

Figure 5 shows the electric lighting performance of the cafe over the course of the first year of data. This yearly representation graphs points colored by a mapping of data to color value intensities and located with hour of the day versus day of the year so that larger trends in the most fine-grained data may be revealed. We note that electric lighting use in the center seems to change with occupancy and availability of daylight, as opposed to the cafe that operates purely based on a regular daily schedule. In the center, note the weekday/weekend patterns and reduced use during summer months.

Figure 6 combines two variables to study trends in air versus surface temperatures. The patterns show strong seasonal variation, with the floor surface warmer during winter when the system cycles in heating mode, and cooler than the air temperature during the warmer months. This behavior is noteworthy since it shows not only that the floor surface could be helping occupants feel warmer in the winter, but it also has the potential to allow them to feel cooler in the summer without mechanical cooling.

Finally, Figure 7 begins to compare the PV and wind turbine technologies by showing the relationship of the output of each system relative to environmental conditions as a scatterplot. Output is normalized by graphing percent of capacity. The predictability and consistency of the PVs becomes readily apparent, as does their ability to produce up to about 85% of their rated capacity. While this definitively shows the poor performance of the wind turbines relative to their rated capacity, more research is needed to identify the reasons for this before conclusions can be drawn regarding this technology.

We note that we gain information using these more advanced data visualizations through abstraction. The context for each graph has become removed in order to reveal behavior. For this reason we see these techniques as fundamentally complimentary to the dashboard and not a replacement.

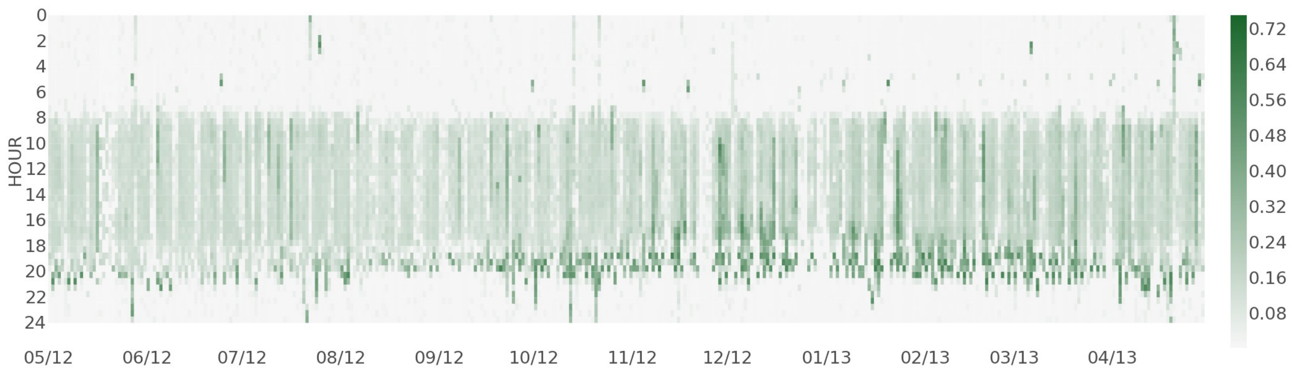

Figure 5 *Hourly graph studying the electric lighting performance in the center for the first year of available data. (W/ft²)*

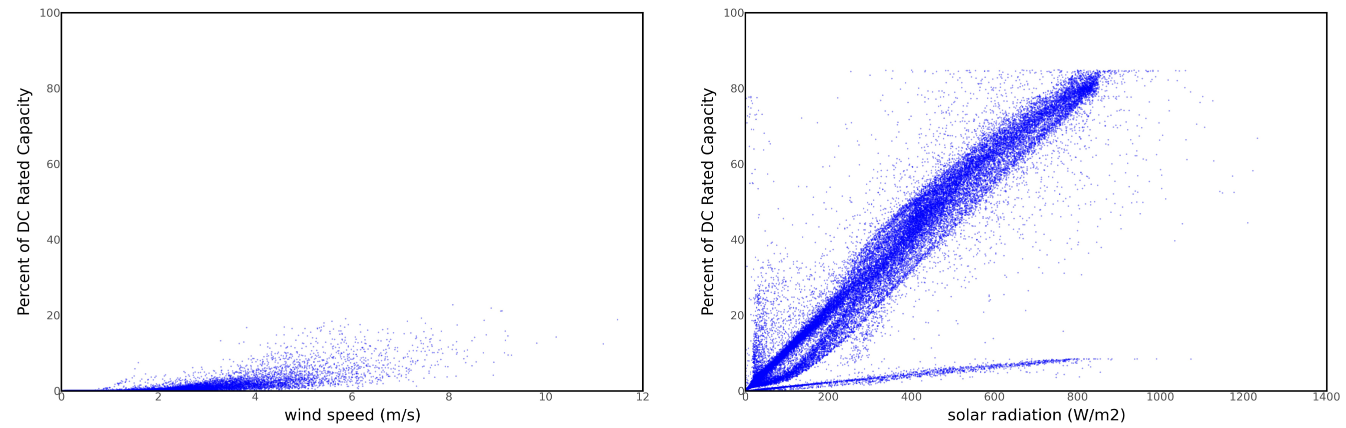

Figure 7 *Scatter plots showing the measured output of wind turbines (left) and photovoltaic panels (right) as a percent of their rated DC output vs. wind speed and global horizontal solar radiation, respectively.*

CONCLUSION

Through the development and implementation of the Crissy Field Center dashboard, we have described features of a monitoring and dashboard system for high performance buildings. First, the monitoring strategy needs to be focused on the aspects of performance defined in a project. For instance, we more fully measure comfort metrics by including both air as well as surface temperatures, but could improve by including sensors to measure mean radiant temperature specifically. Second, for most users, data needs to be represented primarily in multiple contexts, including temporal, spatial, and in relation to multiple variables. Lastly, the data needs to be systematically stored and easily available so that further analysis can be performed to investigate questions that arise while exploring data using the dashboard.

ACKNOWLEDGMENTS

The authors wish to thank our clients on this project: Project Frog as well as Crissy Field Center and the Golden Gate National Parks Conservancy, both of which provided valuable feedback throughout the project development. We are especially grateful for the continued care and interest of Tom Odgers at the GGNPC.

ABSTRACT

It is no secret that architects understand visual representation better than numerical formats. As climate engineering consultants on design teams, it is imperative that design concepts are conveyed in a way that improves the fundamental understanding of the energy concepts and their interactions with various aspects of design. This paper demonstrates through examples, the impact of enhanced graphical communication with the design team, how it results in a better understanding of the energy concepts by the architects, and the design implementation involving building users and operators.

INTRODUCTION

The involvement of climate engineering consultants is often misunderstood to be limited to the energy and daylighting analysis in the design phase. It is equally important for the consultants to ensure a holistic understanding and implementation of the energy design concepts right through building construction. It is imperative for the information exchange between design team members to be precise and devoid of any 'information noise'. Thoughtful and accurate graphical representation is a powerful tool in this kind of assistance. This paper broadly categorizes examples of graphical representation into three areas – context orientation, design influence and physical sensation of energy for building occupants. The impact of this awareness on user behavior is briefly demonstrated.

Multiple examples of enhanced visual representation from practice, such as energy and carbon benchmarking, climate analysis and its comparison with locations familiar to the design teams, various design strategies to effectively achieve the energy balance and incident solar radiation with related shading strategies based on different orientations and façade types are demonstrated in this study.

INTENT AND OBJECTIVES OF ENHANCED GRAPHICAL COMMUNICATION

The primary objective of the enhanced graphical communication in the context of construction industry is to provide accurate information in a concise manner targeted at a specific audience with an ability to be absorbed in an appropriate amount of time based on the design phase and decision making intent.

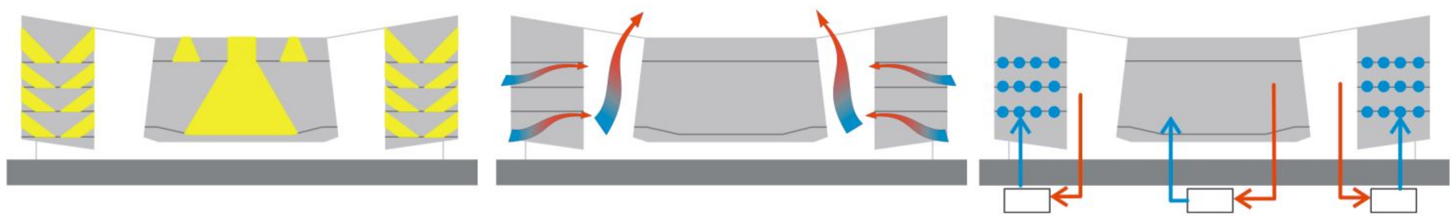

Figure 1 (a) Daylighting penetration in the space. (b) Natural ventilation concept. (c) Radiant heating/cooling concept.

For example, illustrating a climate concept for a competition project presents itself with a unique challenge - the information needs to be self-explanatory so that the judges will be able to decipher it in a matter of the few seconds available to them. In a contrasting example, for an end of phase design report - as a reader can afford to spend the required time to understand and absorb – visual communication needs to be able to deliver detailed information such as the fundamentals of a climate concept or basic physics behind the working of any specific component in the design. Figure 1(a through c) illustrates conceptual diagrams using schematic key sections of a building made for a design competition while Figure 2 shows key results of an exhaustive study involving complex design issues, operating modes and rigorous thermal simulation.

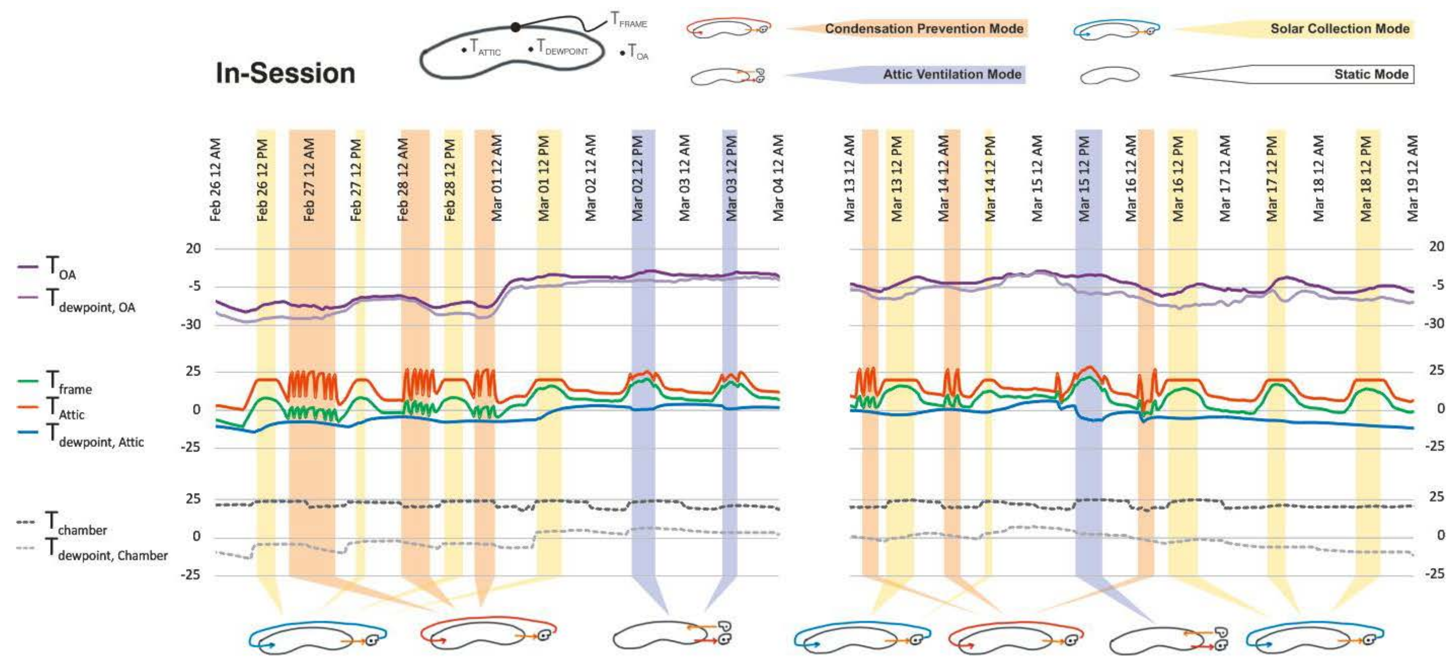

Figure 2 Hourly, daily and weekly variation in outdoor temperature/weather conditions and the corresponding switching between different mechanical operation modes.

PROCESS

In order for the 'integrated design process' to be successful and efficient, it is essential for every team member to accurately interpret information. One way to ensure that the graphical format is clear enough to be understood by a variety of collaborators is by getting inputs from colleagues who come from varying professional backgrounds such as engineering, architecture and liberal arts. For a design driven consulting firm, the toolbox includes design thinking for concept generation and integration, simulation models, custom software, tailored engineering analysis and physical experiments used to develop and validate new ideas. It is equally important then, to effectively communicate the products of this toolbox with rest of the design team for implementation in the actual buildings.

Context Orientation

Context orientation for the purpose of design communication means careful selection and demonstration of precedents and relevant facts related to a project or a study. The intent is to provide a framework for benchmarking and goal setting, highlight challenges and opportunities by filtering out irrelevant information and provide a clear direction for discussion and design thinking on the subject. Figure 3 shows the examples of energy and carbon benchmarking where instead of proposing only a target number, the project potential in relation to the current building stock is provided with an emphasis on 95 percentile and a very aggressive 'PassiveHaus'[1] standard – all in one graph. Heating, cooling and other electric loads are shown separately in the graph as different design strategies can influence each of these energy uses almost in isolation.

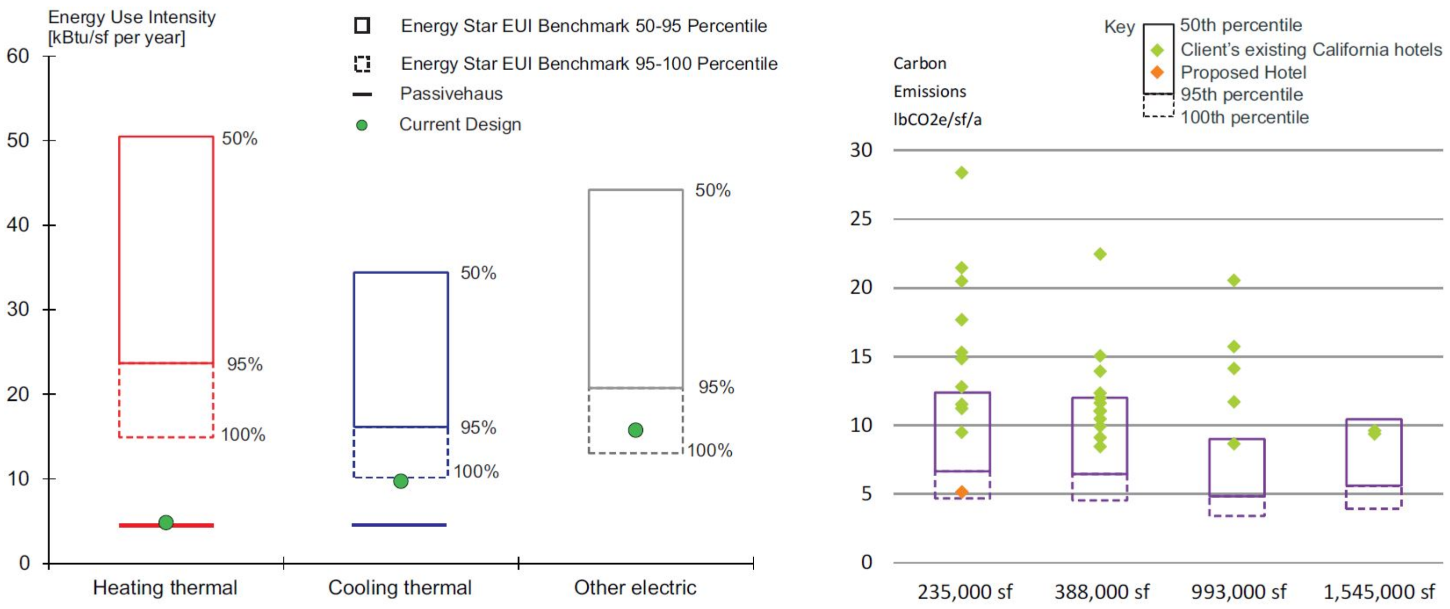

Figure 3 Energy and carbon benchmarking.

Design Influence

Continuous feedback between architects and consultants (with communication materials as simple as hand-drawn sketches to as complex as whole building drawings and energy/daylighting simulation results in Figure 2) is a sign of a truly integrated design process. Most of this communication is geared towards critical decision making. This process can be explained in three key steps: Understand the situation, Evaluate choices and Explain details.

Understand the Situation is about knowing the constraints or boundary conditions for a problem before seeking a solution. For example, the first step in the climate engineering process is to know the local climate for the project. Only after that is understood, can the concept development process begin. Figure 4 shows how this information is taken a step further by comparing climate data for the project location with that of the architect's location. This kind of information has been much appreciated by the architects as they have a 'feeling' for their local climate and find it easier to understand and visualize the climate for the project location due to the graphical comparison.

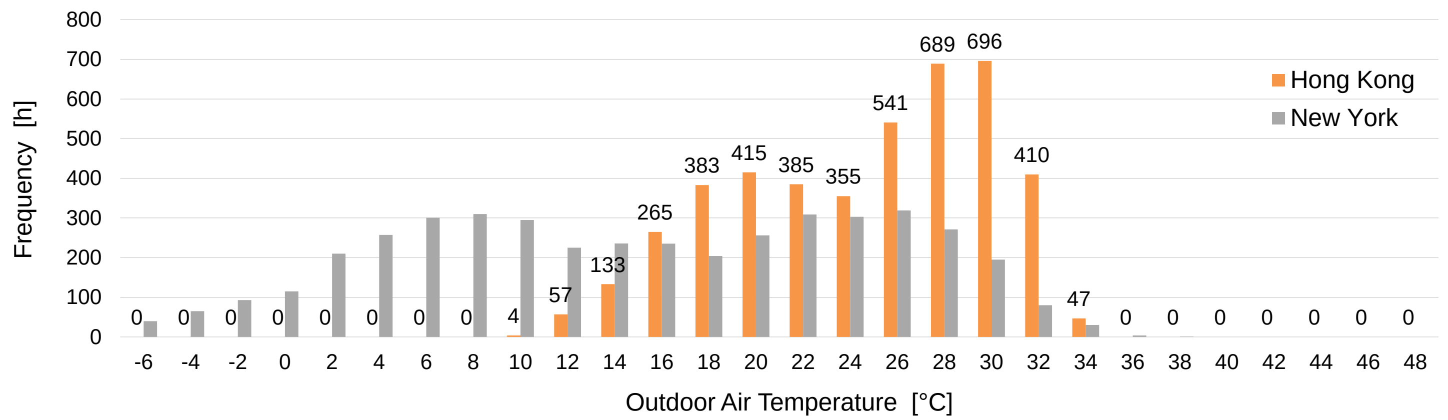

Figure 4 Temperature histogram of the architect's location and the project location.

Another example in Figure 5 demonstrates incident solar radiation data for a project with a continuous curving footprint resulting in various (highly glazed) facade orientations. For the purpose of simplification, all the orientations were approximated into a maximum of twelve. For easier data visualization, a wind-rose format was adopted. A shading projection factor was recommended for all simplified orientations in the same format. A mental comparison of 'solar-rose' with a 'plan view' helps better understand the shading requirements for respective orientations. The final design result was a continuous shading overhang varying in depth as per the orientation derived from this study.

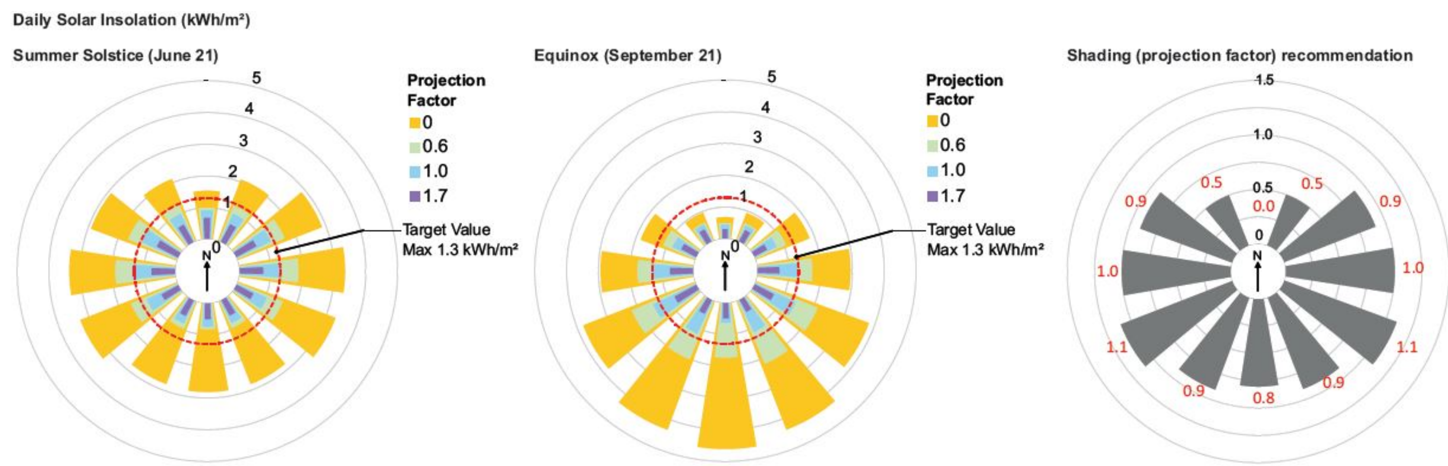

Figure 5 'Solar rose' – Solar radiation data mapped into a wind-rose format and shading projection factor recommendations.

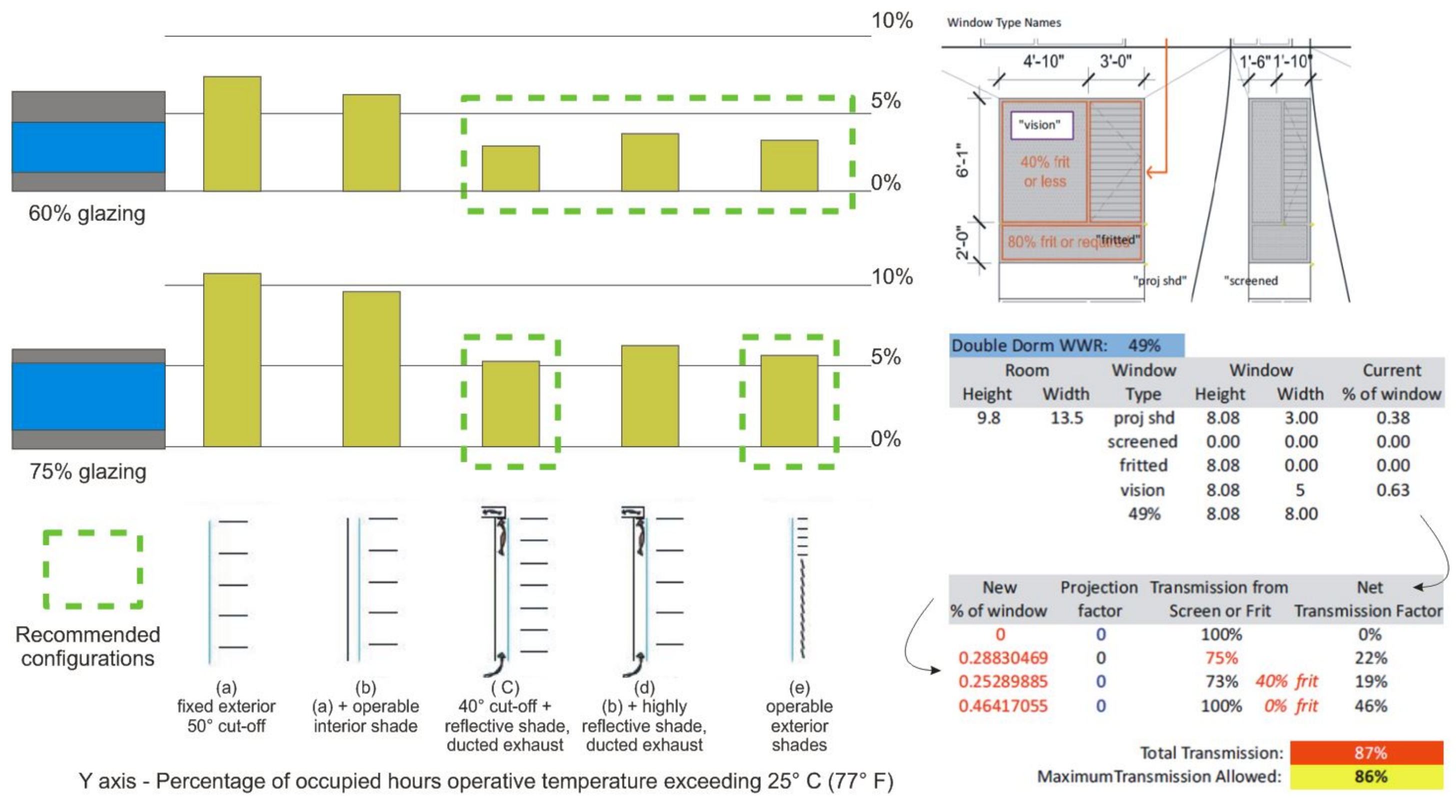

(a) (b)

Figure 6 (a) Comparative comfort study for a 'commons space' façade. (b) Shading transmission calculation tool.

Evaluate choices. In most cases, there is no single 'correct' design solution for a problem but a range of solutions and the task before design teams is to select the desired solution from an available range, based on the given constraints. In the complex process that is building design, there are multiple interdependencies and an ideal decision making process should include consideration and representation of as many critical variables as possible. It is necessary then to present the data in a format which makes a consistent comparison. The critical aspect in this is to make the data visually comprehensible while keeping it scientifically accurate. The goal is to pave the way for exchange of ideas and decision-making based on thorough analysis. The final solution may depend on variables such as aesthetics, user preference, cost and more.

Figure 6(a) Demonstrates results for a comfort study related to a façade configuration for a commons space. Some of the decisions to be made are amount of glazing on the south façade, exterior shading and façade composition. By performing a comparative study with multiple variables, the decision making process is made easier and open.

Another valuable method of effective communication, especially with architects, is to offer a level of flexibility by creating simple and user friendly analysis tools instead of providing end results only. When empowered with an ability to test performance impact of design permutations and combinations in real time, it has helped develop intuition amongst architects. Figure 6(b) shows snapshots of a spreadsheet-based calculation tool which let the architects test different shading transmittances for glazing area on a dormitory room façade. The ability to get results in real-time offered the architects a high level of flexibility within a required framework. The back-end included a combination of results from TRNSYS[2] (Energy simulation software) and spreadsheet calculations. Another significant advantage turned out to be efficient use of time.

(a) (b) (c)

Figure 7 (a) Final shading design as a result of information in Figure5 (b) South façade of a built project as a result of information in Figure 6(a) (c) Rendering of a dormitory room window design as a result of information in Figure6(b)

Figure 7 shows the built projects or projects under construction – for which the design decisions were directly influenced by the studies demonstrated through the graphical representations in Figure5 and Figure6.

Explain Details. During or after the process of decision making, there is often a requirement to validate design concepts; if they work under a variety of boundary conditions and that there are no weak links. It is especially true in case of concepts or products which are unfamiliar to the design team or decision makers. Often a concept might be rejected not because it doesn't work but because the design team or the decision makers do not have a clear understanding of the concept or their concerns haven't been addressed. It is necessary then as a consultant to improve the understanding and instill a level of confidence about the concept with the help of detailed analysis and effective communication. Figure 8 demonstrates part of a detailed study elaborating the effect of various mechanical systems on operative temperature.

Physical Sensation

Physical sensation of energy refers to the experience of physical phenomena such as radiation (solar, radiant heating/cooling) or convection (ventilation) in a habitable space; allowing the building users to appreciate changes in the physical conditions through passive design strategies and by making the invisible, visible. An effective way to improve comfort conditions in the buildings is to provide individual control over the environment and encourage user participation in operation of the building. Providing visual cues to operate windows or to turn the lights off are some of the effective ways (Figure 9).

(a) (b) (c) (d)

Figure 9 (a) Winter garden with operable shading. (b) Man-made cloud installation (c) & (d) Operable window indicators.

CONCLUSIONS

Effective graphical communication results in informed decision-making. From our experience on multiple projects at a global scale, the most valuable benefit of precise graphical representation has been the effective use of design team meetings. It means more time for meaningful collaboration and concept development, rather than analysis explanation. This process encourages understanding of range of options and relative influence of different factors, beyond a single fixed recommendation. Enhanced graphical representation backed by precision of engineering knowledge has resulted in an evolved dynamics of architect-consultant relationship - architects are more inclined to keep the consultant's engagement in a design-focused role rather than an analysis focused role - resulting in superior performance oriented and genuinely integrated architectural design.

The Study of Sky View Factor in Urban Morphologies: Computational Tools and Methods of Analysis

Jennifer Wen Lin Liao, MSc
University of São Paulo

Mônica Marcondes Cavaleri, Post Doc
University of São Paulo

ABSTRACT

Regarding density, many studies confirm that a crowded space cannot be described easily by one single number. Its perception differs from individual to individual, leading to the concept of perceived density. Among the aspects that can influence such perception, the sky view factor (svf) can be highlighted. This paper focuses on the sky view factor and investigates different methods to calculate such parameter in urban design. Several procedures and computational tools were listed and three of them were selected for practical investigation: I) MapInfo and II) Sky View Factor Calculator, both for the analysis of fish eye lens images; and III) DEM (Digital Elevation Model). Three neighbourhoods in Sao Paulo, Brazil, were chosen as case studies for investigation with the selected methods: Cambuci, Bela Vista and República. The results of the case studies and the application of each tool are discussed. As part of the results, unexpectedly lower values of svf were obtained with the DEM analysis in comparison with the fish eye lens methods. DEM allowed for a quick view of the distribution of svf in urban area; nevertheless, it showed lack of accuracy on the representation of irregular surfaces and other obstructions at the pedestrian level such as trees and urban equipment. The fish eye lens methods were more efficient for the analysis of smaller areas with more details; however, its results also depend on the procedure used to calculate the svf. Finally, it was concluded that the efficiency of each method of sky view factor prediction depends on the aim of the specific research; and that the svf is a valid parameter to inform sustainable urban design. Further investigation on the subject is recommended.

1. INTRODUCTION

Many studies confirm that density in urban spaces cannot be described only as a single number (quantity of individuals or buildings divided by area) (Churchman, 1999; Rapoport, 1978). The definition of what is a crowded place can vary from individual to individual, according to their culture, background, location and function. In urban morphologies, additionally to all these aspects, the sky view factor (svf) can be highlighted (Cheng, 2010).

Sky view factor indicates the percentage of visible sky for a specific observer, or, in other words, it indicates the openness of an area (Holmer, Postgard & Eriksson, 2000). The factor varies from 1 to 0, being 1 a completely unobstructed view of the sky and 0 an obstructed view. It is a dimensionless parameter related to two planes: horizontal and vertical. In analyses of urban morphologies, the svf is closely related to the streets' width and the height of obstructions (such as buildings, monuments, objects, trees).

The sky view factor has already shown its importance in solar availability and natural lighting studies. Many researches were developed to facilitate its identification and analysis through computational tools, mathematics, diagrams and graphics, fish eye lens images and image processing tools (Souza, Rodrigues & Mendes, 2003; Ratti & Richens, 2004; Zaksek, Ostir & Kokalj, 2011; Santos, Lima & Assis, 2003).

Aiming to test some of those methods, three case studies were developed in Sao Paulo, Brazil, as part of a major research on building typologies and urban morphology in the city. In the first case, Cambuci, new buildings were proposed and their orientation was analysed for a fixed population density. For the second and third neighbourhoods, Bela Vista and Republica, existing building typologies were studied.

2. COMPUTATIONAL TOOLS FOR SKY VIEW FACTOR ANALYSIS

Three methods involving computational tools were selected for practical investigation regarding the svf: I. DEM (digital elevation model) which was generated by Image J or NIH Image; II. MapInfo; and III. Analysis of fish eye lens images.

2.1. DEM (Digital Elevation Model)

According to Ratti & Richens (2004), DEM is a simplified way to represent urban morphologies. It is visualized in a grayscale plan where each colour determines the height of the pixel. In simple image software such as ImageJ and NIH Image (Ratti & Richens, 2004), it is possible to create a plan and apply different colours to each pixel. The same programs are capable of reading and translating those colours into their corresponding height, turning the 2D plan into a 3D model.

The DEM is an 8-bit .TIFF image in grayscale, with colours varying from 0 to 256. Each plan is created with a lock-up table (LUT) which is similar to a template. It allows the user to attribute a height to each colour. Normally, the grey number 0 is defined as 0m height, grey number 1 equals 1m height, and so on. This makes it easier to change the images’ height without recoloring the entire plan.

It is possible to import images into ImageJ and NIH Image, however, inevitably some colour fixing will be necessary. Both software are able to create macros which allow other types of analysis. Nonetheless, it is also possible to calculate built area through histograms, to create sections of the site and axonometric representations, as well as to visualize the 3D model.

There were found two macros for DEM analyses. The first one was developed by Ratti & Richens (2004) based on a study on building’s shadows. Their aim was to determine the sky view factor by the shadows created by the obstructions. This macro was written for NIH Image, which only runs on iOS system; due to this fact, and because the only system available for the present research was a Windows, it was adopted the second macro developed by Zaksek, Ostir & Kokalj (2011). The latter was developed in ENVI+IDL in a partnership between the Universities of Hamburgo (Germany) and Ljubljana (Slovenia) with the objective of identifying surfaces’ imperfections in geomorphological studies.

2.2 Fish Eye Lens Images

Fish eye lens allow a physical camera to register a field of view wider than regular lens, close to 180° wide. The resulting image is created in a complex process. Firstly, the obstructions (pedestrians, buildings, objects) are projected in a half-hemisphere, or sky vault, which defines the field of view around the lens. Then, such images are projected again in a horizontal plane (Souza, Rodrigues & Mendes, 2003). For the analysis of the first case study, Cambuci, as the model was already built in Google SketchUp, two digital cameras were adopted to generate the fish eye lens images: VRay for SketchUp and Autodesk Ecotect Analysis. For the latter tool, it was necessary to import the model from SketchUp and rebuild it. In the second and third cases studied (Bela Vista and República) the focus was the existing morphology, and thus images were shot with a physical camera.

Computational tools were then used to analyse the obtained images. Generally, such tools divide the sky vault into several parts which are later projected in the horizontal plane. Following, each part is identified as being and obstruction or a part of the sky. The software differ from each other by the way they divide the vault.

Two computational tools were adopted for this phase of the research. The first one was developed by Santos, Lima & Assis (2003) at the Universidade Federal de Minas Gerais and was analysed by MapInfo. The second one, Sky View Factor Calculator, was developed by Lindberg & Holmer (2010).

Other methods were listed; however, due to limitations on time and software availability, it was not possible to assess them all. Among those, it is worth mentioning Souza, Rodrigues & Mendes (2003), which developed a SIG based model created in ArcView. As part of such method, the sky view factor is calculated by an extension called 3DSkyView, which runs together with 3d Analyst, from ArcViewGIS. Once the observer is located, it is possible to generate stereographic and orthographic projections. The obstructions and the visible sky are automatically detected by the extension, which additionally compares the generated image with a stereographic grid of the sky vault, enabling the calculation of the sky view factor. The main reason for not including that method on the present study was the unavailability of a former version of ArcViewGIS, which is required for the 3DSkyView extension to run.

Another tool listed, although not adopted, was CityZoom, developed by SimLab from Universidade Federal do Rio Grande do Sul, in Brazil. This tool is intended for urban design applications (Ely, Lins & Sonza, 2009). As part of the main features, regarding the geometry to be studied, a 3D volume can be drawn directly in the software or a .DXF file can be imported from Autocad. The software can calculate sky view factor by itself without any extensions. It seems to be a fast and friendly tool, but unfortunately it was not available for download by the time this research was ongoing.

2.2.1. Fish Eye Lens Image and MapInfo

Following Santos, Lima & Assis (2003), a fish eye lens image of the area of interest is compared to a template: a grid divided in cells developed by Souza, Rodrigues & Mendes (2003). A number corresponding to a portion of the sky vault is attributed to each cell, as indicated in Fig. 1. The sum of numbers equals 10,000, representing 100% of the visible sky.

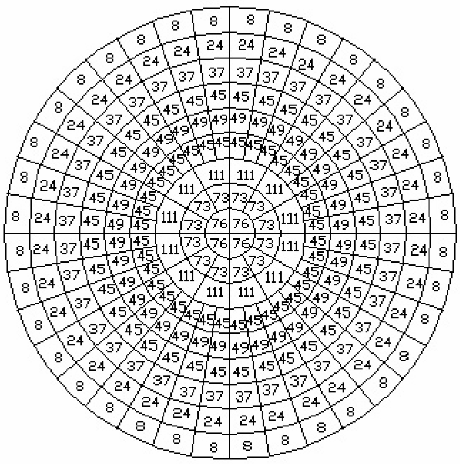

Figure 1. Grid for MapInfo analysis, developed by Souza, Rodrigues & Mendes (2003).

The grid was vectored in Autocad, as well as the fish eye lens image; in the latter case, the obstructed area was separated from the unobstructed one. Using MapInfo (Santos, Lima & Assis, 2003), it was possible to compare the fish eye lens image and the template, resulting in the sky view factor.

2.2.2. Sky View Factor Calculator (Lindberg & Holmer, 2010)

This computational tool was developed in MATLAB, and runs on MATLAB Compiler Runtime (MCR). It can analyse any image file and detect the portion of sky and obstruction automatically. This tool is easier and simpler than the method developed by Santos, Lima & Assis (2003). Once the fish eye lens image is uploaded, the program turns it into a black and white image, where black represents the obstructions and white, the visible sky. Subsequently, the tool can calculate the sky view factor according to two methods.

The first method (Johnson & Watson, 1984) analyses the wall view factor, which is the area occupied by the walls that contour the urban canyons. It was originally used for evaluation of long wave radiation exchange within urban canopies.

The second calculation method (Holmer, Postgard & Eriksson, 2000) analyses each pixel of the image and assigns, to each one, a value representing its percentage in the sky vault. Such portion is related to the angular distance from the centre of the vault. In the present study, the results obtained with this calculation method were discharged due to a great discrepancy in comparison with the results of the other methods.

3. CASE STUDIES: ANALYSIS OF THREE NEIGHBOURHOODS IN SAO PAULO

Sky view factor was predicted and analysed for three neighbourhoods in Sao Paulo: Cambuci, Bela Vista and República. All areas are located in the city centre, have mixed occupation (commercial and residential), urban infrastructure and demonstrate to have potential for an increase in population density.

3.1. Cambuci

The first neighbourhood analysed was Cambuci. A target density was adopted and 16m x 50m buildings were proposed and located in a chosen plot with a minimum distance of 25m between them, according to solar access criteria. For this first essay, the existing buildings, trees and street furniture were discarded. Three scenarios were created and analysed with DEM and fish eye lens images processed with MapInfo method.

For the DEM analysis, the macro was calibrated for a 350 and 250 radius and 180 directions. Each pixel represents 1m distance (Fig. 2).

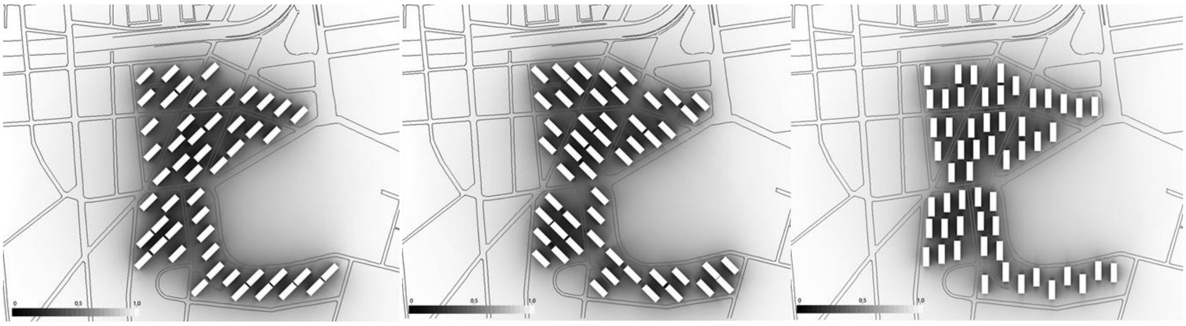

Figure 2. Cambuci neighbourhood, scenarios 1 to 3 analysed with DEM (radius=350 / 180 directions).

Since the scenarios were created in Google SketchUp, firstly fish eye lens images were generated by VRay for SketchUp and by Autodesk Ecotect for comparison between the two results, and latter the images were analysed with MapInfo.

Figure 3. Cambuci neighbourhood: scenarios 1 to 3 with their points of analysis.

Four points located in the centre of each street around the plot were selected for evaluation (Fig. 3). The results of sky view factor can be seen in Table 1.

Table 1. Sky View Factor Analysis for Scenarios 1 to 3 in Cambuci

Scenarios	Point of analysis	VRAY Image + MapInfo	Ecotect Image + MapInfo	DEM (radius:350/ directions:180)	DEM (radius:250/ directions:180)
Scenario 1	1	0.35	0.32	0.22	0.28
	2	0.41	0.29	0.20	0,23
	3	0.34	0.32	0.21	0.29
	4	0.34	0.25	0.22	0.26
Scenario 2	1	0.42	0.34	0.25	0.28
	2	0.33	0.27	0.22	0.23
	3	0.29	0.20	0.18	0.29
	4	0.32	0.30	0.22	0.26
Scenario 3	1	0.34	0.29	0.24	0.28
	2	0.21	0.24	0.21	0.23
	3	0.18	0.25	0.17	0.29
	4	0.20	0.28	0.20	0.26

It is possible to see that, in general, the VRAY image indicated more visible sky than the DEM analyses. However, such lens is more esthetical than technical, and no precise information was found about the type of image generated by this plugin. The results of the fish eye lens images varied from 0.02 to 0.12 in comparison with the DEM evaluation. Despite the different radius adopted for the DEM analysis, the svf results showed some consistency between them and were very similar to the ones obtained with Ecotect + MapInfo.

3.2. Bela Vista

Aiming to study the existing urban morphology, the second neighbourhood analysed was Bela Vista. A block was selected for the investigation and its buildings were catalogued. Fish eye lens pictures were taken directly on site with a camera. Ten points of analysis were selected, comprising all corners of the block and the centre of each surrounding street (Fig. 4). Due to the existence of many trees in the area, it was not possible to determine the svf with the MapInfo method. For this case, it was adopted the Sky View Factor Calculator (Lindberg & Holmer, 2010).

In order to compare results, a DEM was developed for the area (Fig. 5). Since the fish eye lens pictures were taken in pedestrian level (2m from the ground), to build the DEM, the height of the buildings were reduced in 2m. Additionally, the topography in Bela Vista is uneven, and thus its surface was reproduced considering 10cm for each pixel, aiming to improve precision. As a limitation, it was not possible to reproduce trees and other street furniture which are required to accurately represent the area.

Figure 4. Points of analysis in Bela Vista with fish eye lens pictures.

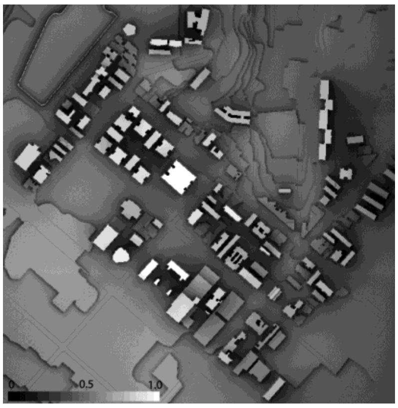

Figure 5. DEM for Bela Vista, at pedestrian level (configuration: radius 380 and 180 directions).

Table 2. Sky View Factor Analysis for Bela Vista.

Point of analysis	Fish Eye Len Pictures + Sky View Factor Calculator	DEM at pedestrian level (radius:380/ directions:180)
1	0.52	0.46
2	0.37	0.43
3	0.22	0.40

8	0.42	0.41
9	0.50	0.38
10	0.25	0.32

Regarding the fact that the DEM did not consider the obstruction caused by trees, it was expected to present higher svf results than the ones from the fish eye lens images (Table 2). Nevertheless, some of the results were similar (see points 4, 5 and 8) and can be justified by: I. The difficulty to calibrate the Sky View Factor Calculator for the representation of the transparency of the trees; II. The lack of precision in DEM, as the 3D model was generated by a city plan provided by the City Hall website; and III. The difficulty to precisely identify in DEM the same points analysed with the fish eye lens.

3.3. República

The method of analysis adopted for the República neighbourhood is similar to the one adopted in Bela Vista. An urban block was selected and eight points of analysis were chosen (Fig. 5). The buildings were catalogued and fish eye lens pictures were taken in loco at pedestrian level with a physical camera. Those pictures were analysed with Sky View Factor Calculator (Lindberg & Holmer, 2010).

Figure 6. Points of analysis in República neighbourhood.

The urban surface in República is more even than the one in Bela Vista, thus the terrain did not need to be reproduced. A DEM at pedestrian level was also generated for that caseand compared to the fish eye lens pictures (Fig. 5 and Table 3).

Figure 7. DEM for República at pedestrian level (configuration: radius 220, 180 directions).

Table 3. Sky View Factor Analysis for República.

Point of analysis	Fish Eye Len Pictures + Sky View Factor Calculator	DEM at pedestrian level (radius:380/ directions:180)
1	0.36	0.26
2	0.30	0.17
3	0.33	0.34
4	0.24	0.23
5	0.26	0.23
6	0.24	0.20
7	0.41	0.30
8	0.16	0.14

Once again, there was a considerable difference between the results obtained by fish eye lens pictures + Sky View Factor Calculator method and DEM. One should expect DEM to show higher levels of visible sky than the former method, since it does not consider street furniture and vegetation, although this theory proved not to be true in both neighbourhoods.

4. CONCLUSION

During the development of this study, the fish eye lens pictures and the Ecotect lens showed sfv with more visible sky than the DEM method. It was unexpected due to the fact that DEM ignores vegetation and street furniture as obstructions, and therefore higher results of svf were expected.

Despite the differences among the results, one advantage of the DEM method for svf analysis is the possibility to obtain a general view of an urban area in opposition to a punctual analysis.

Regarding the results of this research, by analysing the existing morphologies in Bela Vista and República, the average sky view factors were:

- Bela Vista: 0.39
- República: 0.25

Thus, based on the perceived density concept (CHENG, 2010), the República neighbourhood can be said to be perceived by its users as a denser area than Bela Vista. Such result was already expected and it is probably due to the fact that the buildings in the first neighbourhood are placed directly on the front part of the lot, aligned with the street and close to each other. On the other hand, the buildings in the second neighbourhood are placed in the middle of the plot and most of them have gardens in the front part. The streets in Bela Vista were also wider and had plenty of trees, which according to Cheng (2010), helps reducing the perceived density.

Regarding this research, the method used to analyse sky view factor in areas with considerable amount of trees needs to be improved.

In the Cambuci area, the average sky view factor was:

- Scenarios 1 to 3, fish eye lens image from VRay: 0.30
- Scenarios 1 to 3, fish eye lens image from Ecotect: 0.28

- Scenarios 1 to 3, DEM analysis: 0.21

For that neighbourhood, the DEM method showed the lower results. However, for this specific research, related to the analysis of the perceived density, a simplification is suitable and thus the results could be considered as similar, leading to the conclusion that the perceived density in that area is higher than in Bela Vista, but lower than the density perceived in República.

Regarding limitations of the study, glare occurred in the fish eye lens pictures taken with physical camera in Bela Vista and República, which led the software to consider some parts of buildings and trees as part of the sky. The same issue occurred in the buildings covered by glass façades, which reflected solar radiation. *How does this fact effectively affect the perception of density?*

Some unsolved questions remain for a future research, such as the reasons why there were differences between the results obtained in the different methods and aspects of the DEM calibration. Another important issue is the search for methods to analyse the sky view factor in areas covered with vegetation. It was not possible to include trees in the DEM analysis, and the fish eye lens study demonstrated lack of precision.

The sky view factor is a parameter that influences many analyses, such as acoustics, thermic, ventilation and solar radiation (Cheng, 2010). For this reason, it can be emphasised the relevance of understanding the theoretical concepts and relationships among the variables involved in the subject of svf in order to analyse it with more precisely, combining both hypothetical models and existing areas which present multiple types of obstruction.

Roberta Souza, PhD
[UFMG]

ABSTRACT

In tropical countries, such as Brazil, daylight is an important feature used to reduce energy consumption in buildings. However its indiscriminate use may result in situations such as glare and excessive heating of the room. To prevent such unwanted situations and allow natural light in the room, shading devices appear as an important strategy. The Brazilian Regulation for Energy Efficiency of Residential Buildings (RTQ-R) considers shading devices by their effect on the thermal behavior of buildings, not taking into account the artificial lighting energy consumption caused by their presence. In order to study this issue, a thermo energetic behavior investigation was conducted for rooms with different shading devices. Simulations were performed in Daysim and EnergyPlus to get quantitative data about artificial lighting activation and the room´s energy consumption and thermal performance. This article shows the choosing process between the artificial lighting activation systems available in Daysim 3.1, to determine the best one to evaluate artificial lighting activation in residential rooms with shading devices. The studied systems are "switch off occupancy sensor" and "combination on/off occupancy and dimming system" which were named in this study "user-sensor" and "automatic-sensor", respectively. The automatic-sensor is controlled only by occupancy and illuminance sensors while the user-sensor is activated by the user. The results showed that, although the user-sensor demonstrates a situation closer to a real user, the automated-sensor allows a more accurate view of the need of artificial lighting activation. This was evidenced by the greater variance between the increase in energy consumption of rooms with shading devices, in comparison with the model without solar shading, for the automatic-sensor in regard to the user-sensor.

INTRODUCTION

The development of this article was supported by CIE research project (agreement number ECV DTP 002/2011). This project intends to stimulate research development in the field of natural light to collaborate with buildings energy efficiency labelling.

After years of intense and indiscriminate use of energy by man crisis were generated due to resources scarcity. An exemple is the 1970's oil crisis which affected the world economy and draw attention for other sources of energy. In Brazil, the 2001 energy crisis caused energy rationing and affected the country's economy and culture of consumption (BRASIL, 2012). As an important measure

Author A has graduated from Universidade Federal de Minas Gerais (UFMG) with a Master's Degree in the Sustainable Build Environment and Heritage. Author B is an Architecture and Urbanism undergraduate student at UFMG. Autor C is a professor in the Department of Technology of the Built Environment, at UFMG and a researcher at Labcon UFMG.

for energy efficiency, Brazilian government launched in 2009 the Regulation for Energy Efficiency of Commercial, Services and Public Buildings (RTQ-C) and in 2010 the one for Residential Buildings, the RTQ-R (BRASIL, 2010; BRASIL, 2012). These regulations stipulate references for the building's energy performance based on comparative methods and values to classify it as most efficient (level A) or less efficient (level E).

This recent interest in energy efficiency and environmental quality and comfort in buildings has stimulated a return to the use of natural light (ROAF, 2009). Besides the availability during great part of the day, the excellent color rendering index and the possibility of high illuminance levels in the room, natural lighting may be used to reduce energy consumption (CORBELLA E YANNAS, 2003). However, its indiscriminate admission in hot weather buildings may result in unpleasant situations such as glare and excessive heating. These situations lead to immediate solutions which block natural lighting (BOGO, 2009). In this context, shading devices are an important feature to avoid these uncomfortable situations and allow natural lighting integration to the room. However, they need to be designed considering the room's thermal comfort and natural lighting availability.

The importance of using shading devices for thermal comfort improvement has been demonstrated in recent researches such as Sorgato, Versage and Lamberts one (2011). They run computer simulations for a bedroom with shutter and another one without them in a residential building, for four different solar orientations and for the Brazilian Bioclimatic Zone 3 and Zone 8[1]. The results showed that for north and south façades the bedroom without shutters had an average of 32% more degree-hours summation than the bedroom with shutters. For west and east façades the average increase was 82% and 47%, respectively.

A study by Didoné and Bittencourt (2008) on the impact caused by the absence and the use of shading devices in the energy consumption of hotels adopted existing buildings which were not suitable for the investigated climate. The results showed that shading devices blocked the direct radiation and achieved an air conditioning energy saving from 2% to 6%. Besides, this change on the building façade promoted an efficiency natural lighting performance inside the rooms.

Cintra (2011) investigated the influence of the room depth on its daylight autonomy, for openings with and without shading devices. The study was performed through computer simulation in the software Daysim 3.1, for residential buildings, four solar orientations and 11 Brazilian cities. The author concluded that, for the conditions of her study, the maximum depth for a room without shading devices should be 2,6 times the window height, while for a room with shading devices this value should be 2,1 max, i.e., a reduction of 17,9%. Therefore, the presence of shading devices reduces the daylight autonomy of rooms.

In the RTQ-R the presence of shading devices in openings is defined by the *somb* variable and considered in the building envelope evaluation. *Somb* score ranges from 0 (zero) to 1 (one), being 0 for openings without shading devices and 1 only when used shutters (BRAZIL, 2012). Other shading devices, such as *brise soleil*, overhangs and balconies are scored based on two other methods and may receive up to 0.5 points. Thus, shading devices other than shutters cannot reach the maximum score, even though they can perform effective shading during daytime. This happens because the RTQ-R considers shading devices only by their effect in the room's thermal behavior, not considering the darkening of the room caused by their use.

In this context, Soares (2014) developed a study which aimed to improve shading devices evaluation in the RTQ-R. This study is part of a major project from CIE-BRASIL which intends to improve natural lighting issues in energy efficiency regulations in Brazil. Soares (2014) investigated the influence of different shading devices on thermal, luminic and energetic performance of residential rooms, considering Brazilian climate context, through computer simulations. In order to define the influence of shading devices on the room's natural lighting performance, computer simulations were

[1] The geographic limits of Brazilian Bioclimatic Zones (ZB) were delimited according to the bioclimatic strategies recommended for each point on the map of Brazil, based on Givoni Bioclimatic Chart and Mohoney Table criteria. The points with similar strategies were grouped in the same Zone, resulting in a total of eight Bioclimatic Zone, being ZB1 the coldest and ZB8 the hottest.

performed in the software Daysim 3.1.

In this software, user behavior in what concerns artificial lighting and blinds activation is defined by the Lightswitch algorithm. This algorithm was published by Reinhart (2004) and developed based on user behavior observations through field research in private and two-person offices. Based on these observations and in probabilistic analyses, Reinhart defined six artificial lighting activation models, which vary according to the activation (manually or automatically controlled) and the operation mode (on/off or dimmed). Therefore, a deeper investigation about these different Daysim 3.1 artificil lighting models was needed to determine which one would be the best fit for the CIE research. This article presents a discussion about the choosing process of the artificial lighting model to be used for the simulations for Soares' study (2014) about the impact of using shading devices in residential buildings.

METHODS

This study was developed in four steps. First, the artificial lighting activation models to be simulated were chosen. Then, the rooms were defined and at last, the lighting and energy consumption simulations were pereformed.

The system on/off was the most commonly found in residential buildings, therefore this kind of system was sought among Daysim 3.1 possibilities. It was needed special attention in this part as the Daysim artificial lighting models were idealized based on field researches in offices. First, the Daysim models were divided in two groups: the ones manually controlled and the ones automatically controlled. Then, a system from each group was chosen to be analyzed by simulation, according to their main characteristics. Finally, the simulations were performed in order to determine which activation mode, manual or automatic, and which Daysim model would be the best one to verify the artificial lighting activation necessity in residential rooms with shading devices.

The models defined by Soares (2014) were used for the simulations and are described as follows. The simulated rooms were the living room and the bedroom of an intermediate apartment of a condo building. They were tested for four solar orientations (north, south, east and west) and for the city of Florianópolis, representative of the Bioclimatic Zone 3 and classified as Cfa climate by *Köpper-Geiger*. A constant occupation was required to evaluate the shading devices performance in what concerns direct insolation control and daylight availability. The artificial lighting system was determined by a luminotecnic project. The opening area was defined according to the standard set by Guedes (2012) as recurring in residential buildings (15% of the floor area for the bedroom and 25% of the floor area for the living room). At last, different shading devices were selected to be compared to the ones referenced in RTQ-R, as showed in Table 1.

Table 1. Shading devices

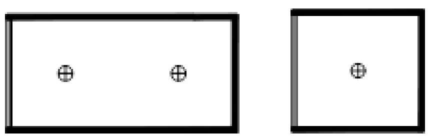
Model	Typology	Description
	No shading device (SP)	Model without shading device (score 0 in RTQ-R), basis for comparison of shading devices performance
	Shutters defined by RTQ-R model (VRTQR)	Shutters defined according to RTQ-R model: always closed for ZB 6 to 8 and closed during spring/summer and opened during autumn/winter for ZB 1 to 4
	Shutters with full opening (V90)	Operable window with two shutters and two glass panes. The full opening of the shutters allows 100% of natural lighting area
	Shutters with opening up to 45% of the total area	Sliding window with one fixed shutter pane, one movable shutter pane and one glass pane. Therefore, the opening for lighting is reduced to 45% of the total opening area

	Shading device defined by the latitud method, described in RTQ-R	Model based on RTQ-R latitude method. It is a simplified method for measuring overhangs, balconies or brise soleil shading
	Shading device defined by RTQ-R Annex 1 method (TN)	Shading device sized according to RTQ-R Annex 1 method
	Shading device which shades during the useful daylight availability period – Whole plate (PTI)	Model defined to shade the room during the useful daylight availability period (Guedes 2012[2]): from 7h40 to 16h20. Composed with one horizontal plate and up to two vertical plates
	Shading device which shades during the useful daylight availability period – Divided plates (PTF)	Model defined as the above, but with divided plates. It intends to investigate the influence of the shading device shape on the thermal performance of the room and the impact of more reflective surfaces in the luminic performance of the room

After defining the models the simulations were performed in Daysim. This software produces a report with metric values for each point of the sensors mesh previously defined. For this study it was used Daylight Autonomy metric to verify when the artificial lighting would be activated, based on the minimum illuminance level demanded by Brazilian regulation NBR 5413 (ABNT, 2013) – 100 lux for both living room and bedroom. The sensor mesh was located together with the lamps in order to verify weather they would be on or off. Therefore, for the bedroom it was used only one sensor, located in the center of the room and 75 centimeters above the floor, while for the living room there were two sensor located in the longitudinal central axis, at the same height (Figure 1).

The V90 and V45 shutters schedule was defined by Daysim dynamic shading model, which predicts that blinds will be lowered when there is excessive glare on the workplane or when direct solar radiation is above $50W/m^2$. The sensors used for this purpose were located together with the artificial lighting sensors. For the RTQ-R shutter (VRTQR) the schedule was defined seasonally, as exposed in Table 1. The static shading devices were drawn as part of the building, within the 3D model. The artificial lighting and shutters activation schedules were used as input data in EnergyPlus to get energy consumption results.

Figure 1. Location of sensors



ANALYSIS AND DISCUSSION

Selection of the systems for simulation

Based on Reinhart study (2004) concerning the comparison of artificial lighting energy consumption between different types of users and activation modes, the main characteristics of each Daysim 3.1 Lightswitch activation models were identified. This is presented in Table 2.

[2] Guedes (2012) defined the useful daylight availability period according to RTQ-R requirement which demands proof of a minimum illuminance level of 100 lux in a room for 70% of a year's daytime. The author considered an average daytime period from 6 AM to 6 PM and selected 70% of this time resulting in the period from 7h45 AM to 16h15.

Table 2 – Daysim 3.1 artificial lighting activation models

Models	Description
Manual on/off near the door	Typical on/off switch system near the door. The user activates the system once a day, when the illuminance level is insufficient. The system remains on for the rest of the occupation hours and the user turns the system off when leaving the office
Switch off occupancy sensor	The system is activated by the user, as the manual system above, but it is turned off automatically by an occupancy sensor
Switch on/off occupancy sensor	Automated model. The system is turned on and off automatically by an occupancy sensor
Photosensor controlled dimming system	The system is activated as in the manual model, but it is dimmed. Therefore, it complements the natural lighting illuminance. However, this model foresees that sometimes the user forget to turn off the system. It happens because is considered that depending on the natural lighting intensity the user might not see that the artificial lighting system is on when leaving the office so the system stays on during the night
Combination switch off occupancy and dimming sensor	Considers an initial manual activation by the user (switch) when one arrives at the office, but with a dimming activation by photosensor. The system is turned off automatically by an occupancy sensor. Therefore, the system is available only when the switch is on
Combination on/off occupancy and dimming system	Automated model which turns the system on and off by an occupancy sensor, but with a dimming activation by photosensor. Therefore, the system is available during the whole time the office is occupied

Later, the activating models were divided in two groups: the systems manually controlled and the ones automatically controlled (Table 2). One system from each group was chosen to be conducted to simulations, aiming to identify which type of control would be the most adequate for the investigation about shading devices impact on the room's lighting.

For the manually controlled group, the **manual on/off near the door** model is activated according to the user's behavior, which, many times, does not take into account the illuminance level. Therefore, it is not indicated for the proposed simulation.

Table 3 – System control modes

Activation mode	System
Manually controlled systems	Manual on/off near the door
	Switch off occupancy sensor
	Photosensor controlled dimming system
	Combination switch off occupancy and dimming system
Automatically controlled systems	Switch on/off occupancy sensor
	Combination switch on/off occupancy and dimming system

The **photosensor controlled dimming system** is not adequate for the proposal because considers an eventual user forgetfulness, as showed in Table 2. Therefore, this activating model does not allow an accurate investigation of the artificial lighting activation. The **combination switch off occupancy and dimming system** was dismissed because even though it considers that the user activates the system by a switch, the lighting is turned on by dimmer. Therefore, it does not represent an on/off system, as highlighted before as the object of study. Thus, the **switch off occupancy sensor** was chosen to represents the manually controlled group, being called in this article user-sensor. This activation model takes into account user behavior and an on/off model.

For the automatically controlled systems, the **switch on/off occupancy sensor** was dismissed because it is activated only according to the occupation, not taking into account the room’s illuminance level. Therefore, the **combination switch on/off occupancy and dimming system** was chosen for the automatically controlled group. In this article, it was denominated automated-sensor. Although this model has a dimming reactor, it was chosen once considers the illuminance level, while the other model considers only occupation. The automated-sensor has automation by photosensor and by occupation, i.e., artificial lighting is activated only when the room is occupied and illuminance level is lower than the pre-determined.

In order to approximate this activation mode to the residential buildings reality, it was estimated on/off activation based on the dimming system results. Thus when the dimming system presented any indicative of activation it was considered the complete activation of the system (100%).

Shading devices sizing

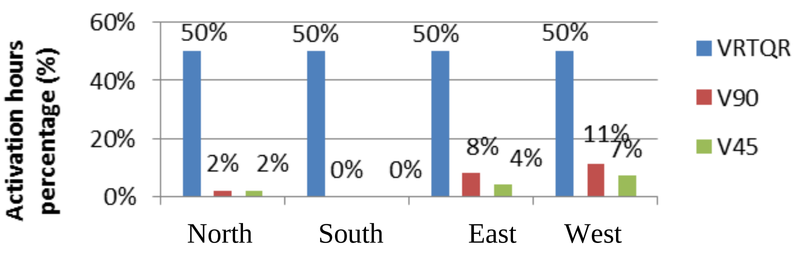
Table 3 shows the sizing of *brise soleil* type shading devices. In general, PTI/PTF was the larger device, followed by TN model. The model L23 was the smallest device.

Tabela 3 – Sizing of shading devices (*brise soleil* type)

	North			South			East			West		
	PTF/PTI	L23	TN	PTF/PTI	L23	TN	PTF/PTI	L23	TN	PTF/PTI	L23	TN
α	59.9°	51.1°	-	16.1°	51.1°	-	78.7°	45.0°	-	78.7°	45.0°	75.0°
βd	44.1°	-	-	9.2°	-	-	-	-	-	-	-	-
βe	44.1°	-	-	9.2°	-	-	-	-	-	-	-	-
γd	-	45.0°	-	-	45.0°	-	15.8°	51.1°	-	72.8°	23.5°	30.0°
γe	-	45.0°	-	-	45.0°	-	72.8°	51.1°	-	15.8°	23.5°	30.0°

Figure 3 shows shutters sizing, represented by the percentage of activation hours in relation to the room’s occupancy hours. It can be noticed that the device with the most activation hours is VRTQR. The other shutters, V90 and V45, presented few activation hours. These results can be explained by the sensor positioning. The shutter sensors were located in the same place as the lighting sensors; therefore it was far from the opening, so the sensor was little affected by direct insolation and excessive glare.

Figure 3 – Shutters sizing



Simulations results

Table 4 shows the activation hours percentage and energy consumption variation for each shading device and activation mode, for the north oriented façade. The other façades had the same caracteristics. The graphics below are a compilation of living room and bedroom results.

Observing the shading devices performance it can be noticed that larger devices, as PTI, PTF and VRTQR, cause greater darkening of the room and, consequently, more artificial lighting activation hours. V45 showed great activation hours because it has a fixed shutter pane which contributes to a greater darkening of the room. Also according to Table 4, it can be noticed that user-sensor caused more activation hours and energy consumption than automated-sensor. However the raise in energy consumption when used different shading devices, when compared to the model without shading devices, was not always higher for the user-sensor. This can be seen in Table 5.

Table 4 – Comparison between energy consumption and artificial lighting activation for user-sensor and automated-sensor for north oriented opening

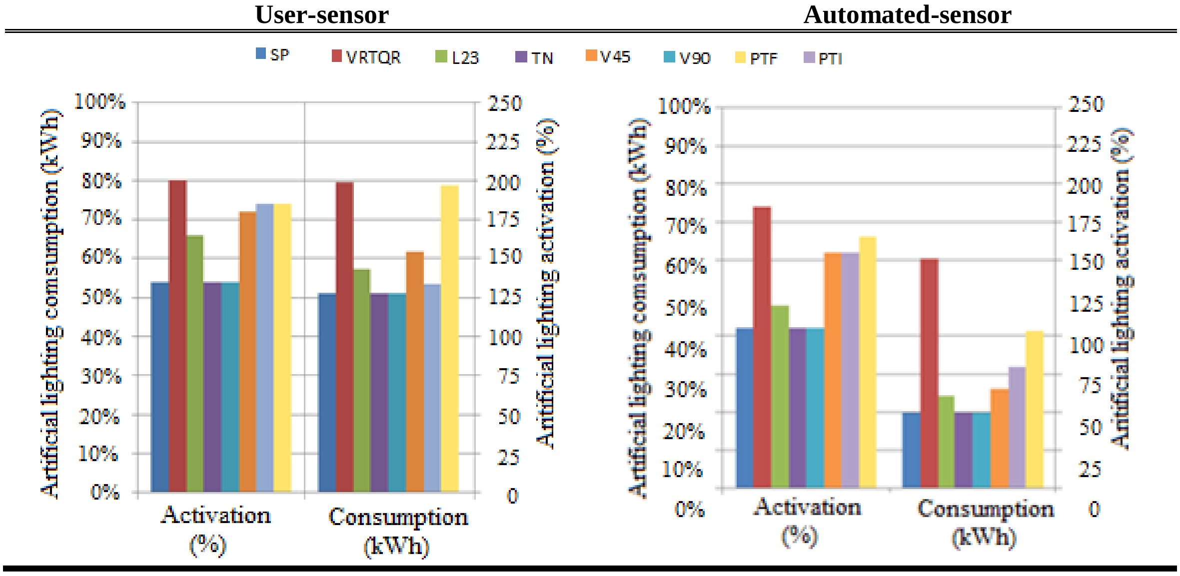


Table 5 – Comparison between user-sensor and automatic-sensor on the raise in energy consumption for the models with shading devices when compared to the model without any device

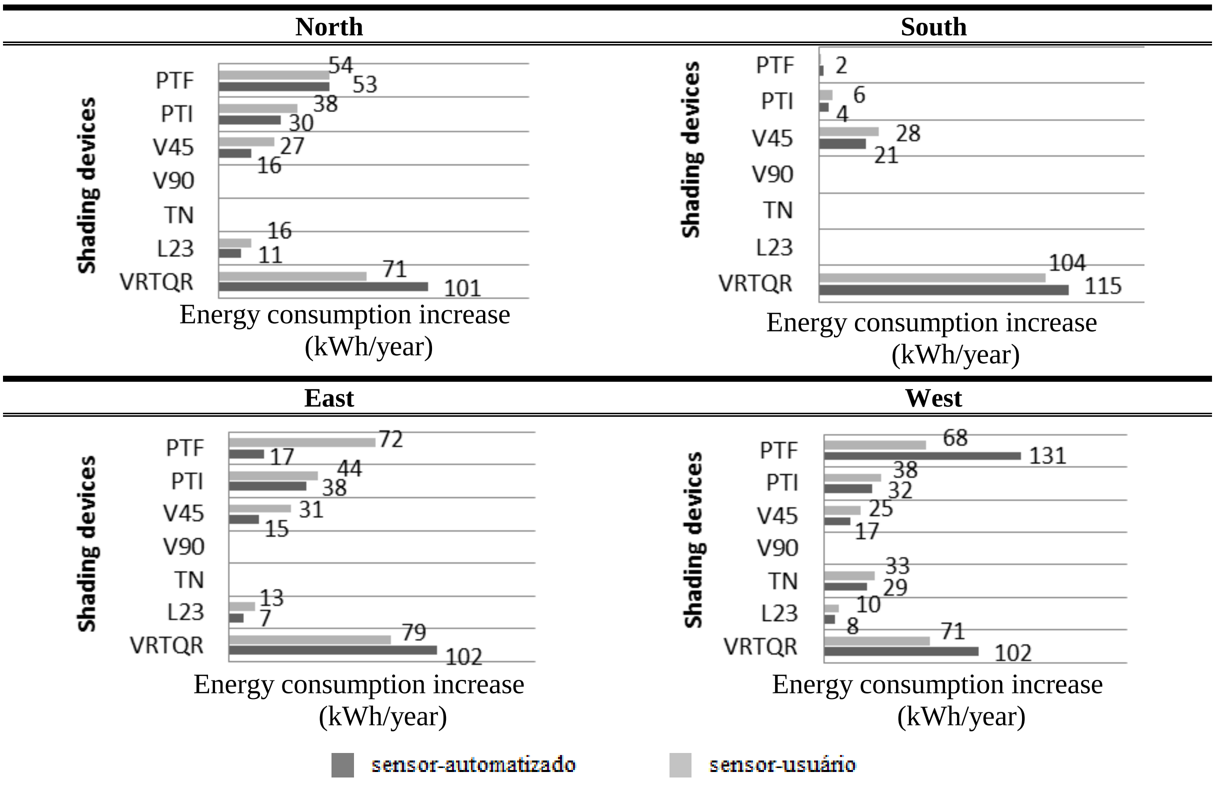

Besides that, it can be noticed a smaller variation in energy consumption raise for the different shading devices when the artificial lighting is activated by the user-sensor than when it is activated by the automated-sensor.

CONCLUSIONS AND FINAL CONSIDERATIONS

In this study two artificial lighting activation modes were investigated and compared in what concerns energy consumption performance: manually controlled systems (user-sensor) and automatically controlled systems (automated-sensor). Based on the systems analyses it was concluded that the automated-sensor represents an idealized user who activates artificial lighting only when necessary to complements natural lighting illuminance, while the user-sensor is closely to a real user behavior.

The results showed that the user-sensor consumes more energy than the automated model. However, when comparing the energy consumption raise when used different shading devices in relation to the base model (without shading device), for each activation model, it was noticed that there was a larger variation for the automated-sensor than for the user-sensor. This can be explained by the fact that the automated-sensor has a variable activation during the day, due to the photosensor. This irregularity in activation results in a higher energy consumption than the user-sensor, as it is needed more energy to activate the artificial lighting system than to maintain it on. In addition, the user role in the user-sensor model tends to reduce shading devices influence on the room's lighting, as the user makes artificial lighting activation more homogeneous, turning the artificial lighting on even when is not necessary.

Therefore, the automated-sensor was chosen to be used on the shading devices lighting performance analyses, once this activation mode allows a more accurate view of the need of artificial lighting activation. It is understood that this article meet the goal of understanding how Daysim 3.1 artificial lighting activation models work and also showed the influence of this choice on the simulation results.

Possible Application of Seaweed as Building Material in the Modern Seaweed House on Læsø

Barbara Widera, PhD
Wroclaw University of Technology, Faculty of Architecture
barbara.widera@pwr.edu.pl

ABSTRACT

The aim of the paper is to present the possible application of seaweed in the contemporary environmentally friendly and affordable architecture. Properly used, seaweed can be an ultimate sustainable material, which is not only available in many areas of the word, but also reproduces itself in the sea and is very easy to gain on the seashore. In some regions, where the quantity of building materials is limited (e.g. Danish islands), seaweed was traditionally used in vernacular architecture. Today, when many countries are threatened with deforestation, we are looking for cheap materials alternative to wood. Seaweed has some important advantages: it is non-toxic and fireproof, provides good insulation, reduces CO_2 emission, has a life expectancy of more than 150 years and, what is also valuable, can be visually attractive. To the top of that, using seaweed can promote the respect for the uniqueness of regional architecture. Some examples of creative and contemporary dwellings made of seaweed as well as the brand new construction methods are presented and discussed in purpose to assess the promising possibilities of rediscovering this forgotten material.

Keywords: vernacular architecture, zero emission, building conservation, low energy materials

INTRODUCTION: ORGANIC MATERIALS IN VERNACULAR ARCHITECTURE.

Gaining building materials from the environment has been one of the most natural architectural concepts from the beginnings of humanity. As pointed by Torben Dahl “Throughout the world, the expressions of traditional architecture are based on and adapted to local conditions. This applies primarily to the local availability of materials and the response to the climatic conditions” (Dahl, 2008, p.8). Locally available, organic or non-organic substance, could be found not only in low-tech constructions but also in very advanced projects, based on the most contemporary technologies. In both cases such material choices increase the connection with local culture, create harmonious composition with the landscape and help reducing transportation. Organic materials deriving from the same climate zone are also well adapted to the climatic conditions.

In vernacular architecture natural materials were used almost exclusively. Today many architects combine them with concrete and steel to achieve modern appearance. In some cases the reason for abstention from the use of natural materials is the awareness of the threat of over-exploitation of the environment. For example the usage of wood needs to be carefully considered to avoid cutting valuable tree species and to maintain a balance of wooded areas, both on the local and the global scale. In some other circumstances the construction system, the functional requirements or even the artistic vision may entail the specific materials, not necessarily natural. Still, it is worth to remember that organic elements of the building also can have a contemporary appearance. Amazing wealth of materials found in nature endows architecture with the unique character. While timber and stone are highlighted in many projects, there is a lot of interesting but almost totally unknown (or forgotten) materials, that may be applied in modern, ecological and affordable architecture. One of such promising examples is seaweed.

Author is a Ph.D. architect, researcher and academic teacher in Wroclaw University of Technology, Faculty of Architecture, Wroclaw, Poland.

SEAWEED CLADDING TRADITION

Nowadays the usage of seaweed in the building industry is observed in very few places in the world. However, it is worth to note that properly used seaweed can be an ultimate sustainable material, which is not only available in many regions, but also, as Jørgen Søndermark noticed "reproduces itself every year in the sea, (…) comes ashore without any effort from humans, and it is dried on nearby fields by sun and wind" (Søndermark, 2013). As a building material it seems to have a great potential since it provides good insulation (which is typical for mineral materials), it is non-toxic and fireproof, and it has a life expectancy of more than 150 years.

In some coastal areas, where the quantity of timber (or even straw) was limited (e.g. on small Danish islands like Læsø), while a lot of seaweed was thrown out by the sea, the eelgrass was used in vernacular architecture, mainly for the house cladding. According to Realdania Byg, the non-profit organization who initiated a preservation project “Seaweed Houses on Læsø”, there were hundreds of seaweed cladded houses on the island. Unfortunately today there are only 36 of such homes left.

Figure 1 The Kaline’s House (dated 1865) on Læsø with traditionally thatched seaweed roof, restored in 2012 by Realdania Byg. Photographer: Helene Hoeyer Mikkelsen/Realdania Byg (2012).

PRESERVATION PROJECT ON LÆSØ

In the continuation of efforts for preserving the cultural heritage of the small region of Læsø, in 2012 Realdania Byg organized the restoration of 150-year-old Kaline’s House on Læsø, with traditionally thatched seaweed roof. Simultaneously the same group launched the architectural competition with a goal to design the modern house on Læsø, referring to the local tradition but offering the contemporary standard. The Vandkunsten architectural studio, who won the competition, developed a very creative and contemporary dwelling made of seaweed. As a consequence the Modern Seaweed House on Læsø was built in 2012-2013, according to the project of Vandkunsten studio in cooperation with Realdania Byg. The designers decided to use the seaweed as a traditional material but they also proposed the new technology and the brand new construction method.

In vernacular structures the seaweed was placed directly on the roof, one layer after another, to provide the demanded thermal insulation and impermeability. Within years new layers were added and some roofs became very thick, they would even reach the thickness of 1,5 meter. The drawback of that system was not only the size, but also the weight of the roof, with the increased risk of collapsing. Although some of the houses could be perceived as beautiful from outside, the visual comfort of the user was often disturbed by small windows, additionally shaded by many layers of seaweed, that would block the sunlight penetration into the living areas of the house as shown in **Figure 1**.

THE CONTEMPORARY DWELLING MADE OF SEAWEED

The authors of the Modern Seaweed House on Læsø carried out Environment Behavior Studies (EBS) in purpose to use vernacular architecture as a model, as suggested by Rapoport, and consequently to improve the solutions observed in vernacular buildings instead of copying it directly (Rapoport, 2006). To provide the functional and comfortable dwelling the architects focused on the value of natural light and space. They developed the summer holiday residence with a big common space in the center and some smaller rooms on both sides of the building. The house is heated with a highly efficient heat pump, placed in an adjacent shed that can also be used as a storage (e.g. for bikes and kayaks). The building is tight, well insulated and fitted with an effective mechanical ventilation system with heat recovery. Due to the proper insulation it is possible to maintain constant temperature of minimum 10˚C throughout the winter, so that the house is frost-free.

Figure 2 The Modern Seaweed House (2012-2013) on Læsø, designed by Vandkunsten in cooperation with Realdania Byg. Photographer: Helene Hoeyer Mikkelsen/Realdania Byg (July 2013).

The light construction was designed without steel nor concrete. Instead, to emphasize the unique spirit of the island, the sea plant from the family Zostera marina was used as a building material i.e. as an insulation for ceilings, roofs and walls. As shown in **Figure 2**, in some elements it was introduced in the clearly visible form, while in others it is slightly hidden, both for functional and esthetic reasons.

The most obvious application of seaweed was the roof cladding shown in **Figure 3a**. Nevertheless, it was necessary to propose the brand new technology to achieve the lightweight and contemporary looking roof. On the other hand it was equally important not to lose the ambience of simplicity, connection with the environment and the obvious utilitarism, that stood behind the usage of the natural material that could be found on the beach. Therefore the seaweed was stuffed into the nets knitted from a woolen yarn as shown in **Figure 3b**. Each element is 6-8 meters long and closed at both ends. These nets were attached to the façade and to the roof, where they formed the original and expressive finishing. At the same time, the seaweed filling was placed inside the wooden cassettes made of low processed timber and divided into smaller inner sections. These prefabricated building modules formed the house framework and provided an excellent insulation of floors, walls and ceilings with the λ value 0,0376 W/mK (Pedersen, Ransby 2005, p.4). Another innovative application of seaweed was inspired by traditional mattresses. The dried seaweed was used for internal finishing elements, which are stuffed with eelgrass and covered with natural colored linen so that they slightly resemble the mattresses as shown in **Figure 4a**. These elements were used for internal wall cladding. The bright linen corresponds well to the timber color and gives the interiors light and natural appearance as shown in **Figure 4b**. Furthermore such used seaweed has exceptionally good acoustic properties.

Another seaweed feature, which is very useful in building, is the ability to absorb and give off moisture. That contributes to the regulation of indoor air humidity parameters. Various solutions, based on the seaweed application, created truly comfortable interiors with high-quality indoor microclimate. The list of possible variants of seaweed implementation can be developed further, in purpose to expand

the prospective options for affordable sustainable building. The Modern Seaweed House has a very low energy consumption and due to the fact that the organic materials were used almost exclusively, the house accumulates more CO_2 than it was emitted within the whole process of production and transportation of the building materials (Realdania Byg, Walther, 2013).

THE LIFE CYCLE ASSESSEMENT FOR THE MODERN SEAWEED HOUSE ON LÆSØ

In purpose to assess the potential for the application of seaweed as a sustainable material for the contemporary, ecological and affordable architecture the Life Cycle Assessment (LCA) was carried out by Kauschen (Kauschen, 2013).

In general LCA is a technique that allows to assess the environmental aspects and potential impacts associated with products and processes by:

1. Compiling relevant energy and material inputs and environmental releases
2. Evaluating potential environmental impacts connected with identified inputs and releases
3. Interpreting the results for making more conscious decisions (EPA, 2006, p.2).

LCA method evaluates all stages of product's life and includes all phases necessary to produce, operate and dispose a building ("cradle to grave"). The phases are divided into raw material acquisition, building materials and/or component production, use and maintenance, waste management ("End-of-Life"). The applied "End-of-Life" method includes also the possibility of recycling. In accordance to ISO14040 standard, the research involved:

1. Goal and Scope defining (at this stage the assessment context was established, the boundaries and potential environmental effects were identified, a functional unit as a reference value for the assessment was defined);
2. Life Cycle Inventory (LCI, i.e. the inventory analysis which identifies and quantifies energy, water and materials usage and environmental releases) with the model based on building description, drawings and data extraction from BIModel (Revit).
3. Life Cycle Impact Assessment (LCIA) that allows to assess the potential ecological effects and refers to all inputs and outputs defined in the inventory analysis.
4. Interpretation of the inventory analysis and impact assessment in purpose to select the products and processes "with a clear understanding of the uncertainty and the assumptions used to generate the results" (EPA, 2006, p.2). In this stage the results were interpreted and validated.

The categories and calculation methods used in LCIA match DGNB standard (DGNB, 2010), as a DGNB Denmark (Danish adaptation of German standard DGNB, Deutsche Gesellschaft für Nachhaltiges Bauen), is a standard certification system for sustainable building in Denmark (Green Building Council Denmark, 2012). The impact categories and characterization factors are based on CML 2001 method, developed by the University of Leiden (Guinée, 2002). The environmental data was taken from ökobau.dat database (2011). For new processes (already not existing in ökobaut.dat), the assumptions were based on similar processes from Ecoinvent database (2.2), information from experts and producers Environmental Product Declarations (EPD). The Excel tool developed for the calculation of the product system was based on the method described in DGNB manual (DNGB, 2010). It should be mentioned that this LCA was carried out to identify potential environmental impacts with a goal to optimize the project in these terms and no critical review was undertaken. Thus the assessment can be classified as the life cycle screening (hot-spot analysis) instead a full LCA according to ISO standard 14040. The following impact categories of the seaweed building were analyzed: global warming potential (GWP100) [kg eq. CO_2], ozone depletion potential (ODP) [kg eq. R11], photochemical ozone creation potential (POCP) [kg eq. C_2H_4], acidification potential (AP) [kg eq. SO_2], eutrophication potential (EP) [kg eq. PO_4], non-renewable primary energy demand (NPED) [MJ], renewable primary energy demand (RPED) [MJ], total primary energy demand (TPED) [MJ], water usage [t], waste production [t], hazardous waste production [t], abiotic resource depletion [t], excavation residues [t]. For the LCA calculations the functional equivalent of a holiday property was set at $86m^2$ gross floor area, $30m^2$ loft and $124m^2$ terrace. The house has up to 10 beds and is used 168 hours a week, whole year, for

50 years (Kauschen, 2013, p.7). The building includes about 200 components and 38 different materials, which are divided into different building elements shown in **Table 1 and 2**. Electric air-water heat pump is used for heating and hot water preparation. The BE10-calculation shows a total energy requirement of 64,4kWh/m^{2}a, while the total electrical energy need is 54,4kWh/m^{2}a. BE10 is the software developed by the Danish Building Research Center (SBI), mandatory to be used in Denmark for energy calculations for reference purposes.

To check the environmental impact of the holiday house three energy scenarios were proposed: without operational energy; operating with energy from DK wind power; operating with energy from DK Grid Mix **(Tables 3,4,5)**. The option to use wind power was the most interesting since there is no need to produce renewable energy in the holiday house itself. Solar energy was not taken into account as the house is situated in the shadow of the forest and also because the photovoltaic panels would not fit to the concept of the seaweed roof that should preserve the unique spirit and heritage of the place.

CONCLUSION

The LCA analysis of the Modern Seaweed House on Læsø proved that with the proper insulation and the usage of wind energy the building has negative carbon footprint and minimal potential environmental impact throughout the assumed lifetime of 50 years. The conservative approach to the data selection for calculations was chosen, especially regarding the End-of-Life scenarios. Such conservativeness reduced the risk of obtaining too favorable assessment which could lead to the erroneous interpretation. In most impact categories the outcome is determined by the type of energy supply. The presented results of calculations carried out for scenarios 2 and 3 show the impact of the choice of the energy source on the environmental performance of the building. In the majority of cases DK wind power energy scenario allows to achieve much better results in comparison with DK Grid Mix energy scenario. The values achieved in scenario 1 proved a very low level of the environmental impact of seaweed used as the building material in the Modern Seaweed House on Læsø.

Due to the continuous emission of CO_2 to the atmosphere, the amount of seaweed in the seas and oceans is actually increasing. That should put our attention on this plant as a potential building material and a source of energy, especially today, when many countries are threatened with deforestation and we are looking for cheap materials alternative to wood. The important advantages of seaweed should be widely recognized: it provides good insulation, great acoustics, humidity control, visual comfort and the reduction of CO_2 emission. It is also non-toxic, fireproof, low-energetic, biodegradable with a life expectancy of more than 150 years. The seaweed is covered with the sea salt and thus naturally protected against bacteria or insects that could destroy the structure. However, it is important to note that seaweed is such a good material choice when it is harvested naturally, i.e. collected on the beach, dried on the meadows (not in ovens) and transported on short distances only. Used that way seaweed can promote the respect for the uniqueness of regional architecture but simultaneously can be easily adapted to the specific local conditions, including different cultural and climatic factors. This is in accordance with the statement of Peter Sørensen and Winnie Friis Møller that “Architecture is a connecting link between place, climate and human life” (Sørensen, Møller, 2008, p.13).

Finally, what is also valuable, seaweed can be visually attractive and its usage allows to establish the balance between the traditional and modern architecture. The preservation initiative of Realdania Byg helped to involve local community into the process which increased the awareness both of the natural and cultural heritage of the island. Consequently that leads to the protection of the architecture of the past and at the same time to the development of the sustainable architecture of the future.

ACKNOWLEDGMENTS

The author wishes to express her thanks to the non-profit organization Realdania Byg who build and preserve the seaweed houses in Denmark, Jørgen Søndermark and architectural studio Vandkunsten who designed the Modern Seaweed House on Læsø, Jan Schipull Kauschen who carried out LCA analysis and the photographer Helene Hoeyer Mikkelsen, Realdania Byg.

ABSTRACT

Urban spaces in tropical country like India have always been the focus of socio cultural activities. In recent times these activities are stressed by increased urbanization. Among many factors that influence outdoor ambient temperature (traffic, pollution, population density…) the building surface treatments have also contributed in challenging the urban micro climate. Insufficient open spaces, diminished wind movement and strong irradiation from the high rise densely packed built environment has very much reduced the quality of urban outdoor life. Though there are many individual studies on the built form and building material influence on urban micro climate, they seldom give comprehensive guidance to the city designers, essentially the planners and the individual architects.

This paper investigates the influence of building materials on the micro climate of urban commercial streets (pedestrian users) by comparing their thermal performances. The study also tries to explore possible design interventions to minimize the impact of the building materials on the urban micro climate. Henceforth the outcomes will create cognizance among the designers to evolve climate sensitive design and material choice. Urban Micro Climate - Building Materials - Design Solution. The inferences in this paper will enable the architects and planners to design buildings with the understanding of their response to the urban microclimate and comfort of the pedestrian users.

KEY WORDS Urban Microclimate, Building Materials, Heat Transfer, and VASARI

INTRODUCTION

The phenomenon of city - induced environmental change has been known for many centuries. The ancient Indian Architectural manual “Silpa Sastra”(translated by Acharya 1979) laid out rules for the siting of villages, towns and forts based on prevailing wind directions and solar orientation.(Rohinton Emmanuel,2005). The city design is basically composed of many elements like the buildings, open spaces, networks (roads, streets, pathways, and bridges), traffic (vehicle & pedestrians), and vegetation. The inter relationship among these elements influence the quality of the urban environment. Though there are many factors that define the quality of urban life (environmental, functional, and aesthetic) this paper focuses on the environmental quality of the cities.

A large number of road users in India are pedestrians. (Gururaj G,2006)(Peden M, Scurfield R, Sleet D, Mohan D, Hyder AA, Jarawan E, et al.).The environmental comfort of the pedestrian users is seldom given a thought by the planners, developers and designers. The factors that influence the outdoor thermal comfort of the pedestrian users can be broadly classified as the **Climatic Factors** (Solar Radiation, cloud cover, precipitation, wind speeds, Humidity, and air temperature) and the **Physical Factors** like (orientation, Aspect Ratio, Vegetation, Sky View Factor (SVF), Building Materials) (Oke et al., 1987 and Santamouris, 2001). The influence of the building materials on the urban microclimate focusing on to the pedestrian users and the possible solution is a part that still needs to be explored by the planners and designers.

Hence the aim of this paper is to analyze the building material contribution on the urban microclimate, specially focusing on the pedestrian users. The result of the analysis enable in arriving strategies to improve the microclimatic condition as this will facilitate the architects and planners to design buildings with the understanding of their response to the urban microclimate and comfort of the pedestrian users.

METHODOLOGY

To evaluate the influence of building materials on the urban microclimate of the pedestrian user's two commercial streets of the CBD (Central Business District) is chosen with different orientations. The surface radiation in the streets were calculated for five different time periods. The climatic data was calibrated with an Infrared Thermometer, air temperature and wind speed was calculated with hand held devices. The radiation of the surfaces were calculated through the Stephen Boltzmann Constant. The radiation values were mapped. The radiation values of the individual materials were analyzed for surfaces with different orientation and aspect ratio. The result of the comparison enabled this study to derive strategies that would assist the designers and planners to work on options so as to minimize building material influence on the microclimate the urban pedestrian users. Since the study area is a CBD there was no scope for vegetation. Hence the impact of vegetation on the microclimate of the study area is not considered.

SITE DESCRIPTION

The study was conducted in Tiruchirappalli City (Tamil Nadu , India) located at 10° 48' North and 78° 41' East. The city is at the altitude of 88 m above sea level. The climate of Tiruchirappalli is Hot Humid. The state of Tamil Nadu has a clear climate change scenario. The study was done in the month of April - 2013, based on the IMD report April month has recorded the highest. (*State Level Climate Change Trends in India, Meteorological Monograph No. ESSO/IMD/EMRC/02/2013)*.

Traffic Pattern

The commercial streets (NSB Road, Big Bazaar Street) of the CBD (Central Business District) of Tiruchirappalli City was chosen for the study. The streets are both high density and high rise in character with no scope for vegetation. These streets are significant because they are mostly used by the pedestrians. At the time of festivals like Deepavali and Pongal the streets are completely pedestrianized.

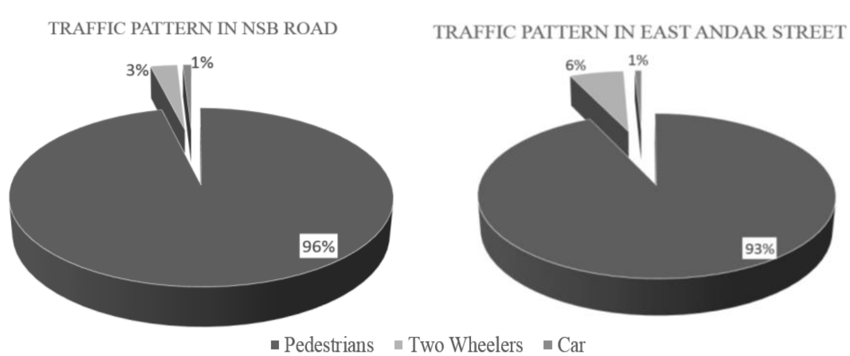

Figure1: Shows the traffic pattern in (a) NSB Road,(b) Big Bazaar Street.

(Source: Tiruchirappalli city Traffic Police)

The buildings of both the NSB road as well as the Big Bazaar Street are of different heights and different surface treatments. The common material used on the building skin are the Aluminum composite panel, Structural glazing (both doubly as well as single glazed layer) and Cement plastered wall with paint. The road surface is made of asphalt.

Solar Access

The urban microclimate is influenced by many anthropogenic induced factors like Pollution, High density construction that cause less wind (A.M. Papadopoulos 2001, B. Givoni 1998) , building material choice (H.Taha,1997),Orientation of buildings,streets (M. Santamouris, N. Papanikolaou ,2001),Lack Of Shading(L. Barring et.al ,1958),Canyon Geometry (S. Yamshita , 1986). The incident solar radiation influences significantly on these anthropogenic factors. Unlike the western countries the right to solar radiation has to be controlled in Tropical country like India to achieve an ambient urban microclimate. The incident solar radiation contributes significantly to the heat transfer phenomenon of the building materials (C. Conner, 1985).

The urban canyon is a more useful city unit for the study of the microclimate of urban environment.

The energy balance of the ‘Earth surface’s – ambient air’ system in the urban environment is governed by the energy gains and losses as well as by the energy stored in the opaque elements of the city, mainly buildings and streets.(M.Santamouris,2001)

$$\textbf{Energy gains = Energy losses + Energy Storage} \qquad (1)$$

Incident solar radiation values are based on two primary components: Direct Radiation from the sun (direct bean radiation = I_b which is always measured perpendicular to the sun's rays. Diffuse radiation that is both scattered by the clouds and atmosphere (diffuse sky radiation = I_d) and the ground in front of the surface (I_r).This is always measured on a horizontal surface.

i.e $$\textbf{Incident Solar Radiation} = (I_b * F_{Shading} * \cos ø) + (I_d + F_{Sky}) + I_r \qquad (2)$$

Where: I_b = direct bean radiation
I_d = diffuse sky radiation
I_r = radiation reflected from the ground
$F_{Shading}$ = Shading factor (1 if a point is not shaded, 0 if a point is shaded, a percentage if measured on a surface)
F_{Sky} = Visible sky factor (a percentage based on the shading mask)
Ø = angle of incidence between the sun and the face being analyzed.

Heat Transfer

The heat transfer phenomenon between the buildings and the environment is very complex (R. Priyadarsini and N.H. Wong, 2005). This phenomenon can be defined on the basis of three basic parameters (A.M. Papadopoulos,2001):

1. The insolation of the buildings, which is a direct function of the orientation, the morphology of the building and the shading factor due to opposite buildings and the existing shading devices;
2. The wind flow in the street canyon that depends on the road's orientation in relation to the prevailing wind direction, the geometric characteristics of the canyon and the temperature conditions on the surfaces of the buildings and the road; and
3. The additional heat emission from local points like the air conditioning systems and the road traffic.

Temperature and Radiation

The three main methods of heat transfer resulting in change of temperature are conduction, convection and radiation. All bodies with a temperature greater than absolute zero radiate energy. Absolute zero is the temperature at which there is no molecular or atomic random motion. It's denoted by 0 Kelvin degrees, which is equivalent to -273.15° C or -459.67° F. Late in the nineteenth century, Stefan experimentally and Boltzmann theoretically developed a relationship between the temperature of a body and the amount of power it radiates.:

To determine outgoing radiation power, we utilize the Stefan-Boltzmann Law

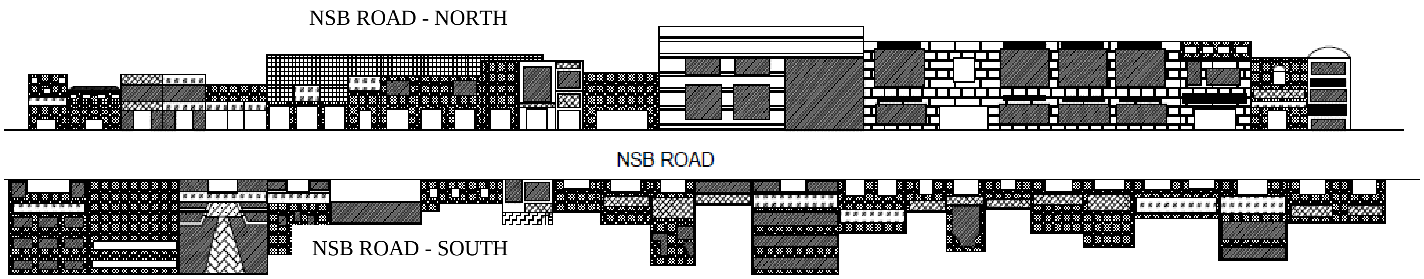
$$P = A\,\varepsilon\,\sigma\,T^4 \qquad (3)$$

Where P (watts) is the radiated power from a body of area A (m2) at temperature T (K).
ε is emissivity
σ is the Stefan-Boltzmann constant, 5.67*x*10-8 Wm-2T-4
T is the body temperature in Kelvin.

Hence the radiation emitted by buildings, streets and all emitting surfaces in the canopy layer can be calculated through the Stefan-Boltzmann Law (M. Santamouris ,et al. , 2001)

Material Map

The materials of the streets are mapped and the area for the individual materials are calculated, the surface temperature of the materials are measured for five different time period (7.00 am,11.00am,13.30 pm,15.00 pm,17.00 pm).



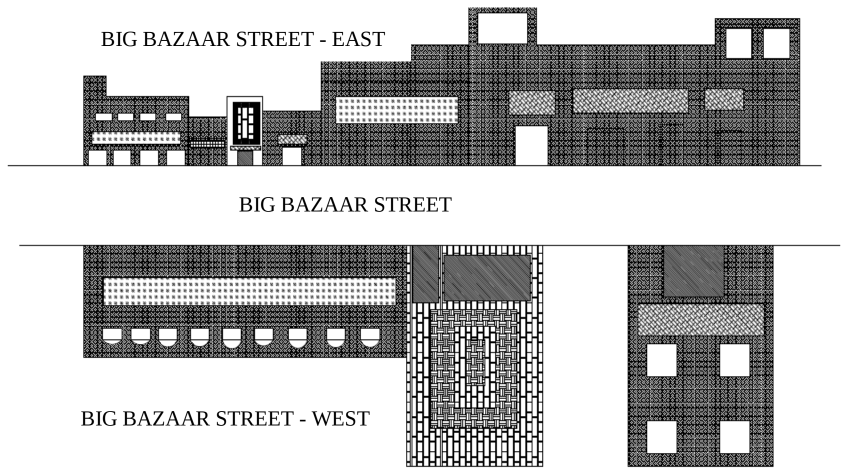


Figure 5: Shows the materials map on the building façade - the streets in elevation.

Observation

The documentation of the building in NSB Road and the Big Bazaar Street resulted in thirteen different materials. (Table 1).

When the radiation of the materials were calculated using Stephen Boltzmann Law, it was observed that due to more emissivity value and substantial percentage of usage in the surfaces, concrete and asphalt contribute significant radiation for all the five time periods analyzed. The radiation value of concrete range between 0.0841W to 0.0878 W and that of asphalt range between 0.042 W to 0.046 W (**Figure 6).**

S.no	Material	Area
1	Concrete	5727.3
2	Glass	1477.14
3	Plastic Board	626.1
4	Flex	674.8
5	Metal	142
6	Granite	9.9
7	Asphalt	2722.9
8	ACP - white	286
9	ACP - Red	87.3
10	ACP – Grey	1391.3
11	ACP - Gold	186.2
12	Gypsum – White	20.3
13	Gypsum - Gold	39.7

Table 1: Shows the materials and the area on the building façade.

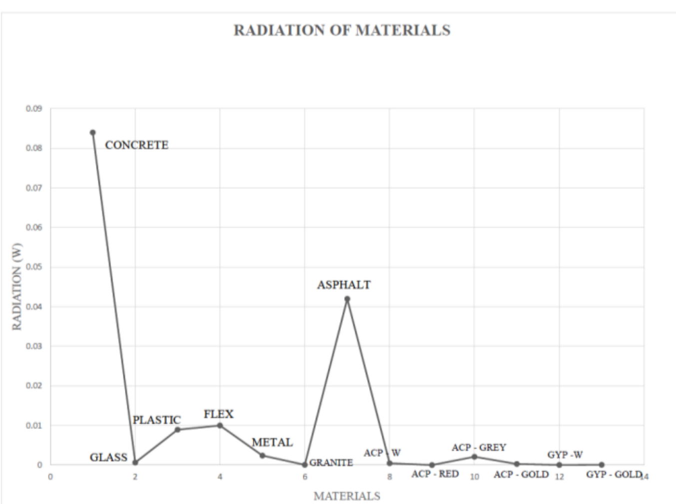

Figure 6: Shows the radiation value of the materials

The surface temperature value of the materials in the NSB Road (East – West orientation) was 3° C more in comparison with that of Big Bazaar Street (North – South Orientation) and this difference was more significant in the early evening time (15.00 pm) when the materials start reradiating the incident radiation. Hence it was evident that the materials in particular, **concrete and asphalt** influence the microclimate of both the streets.

Street Geometry – Materials – Urban Microclimate

This study further explored the relationship between urban canyon and urban microclimate. There were very interesting relationships observed.

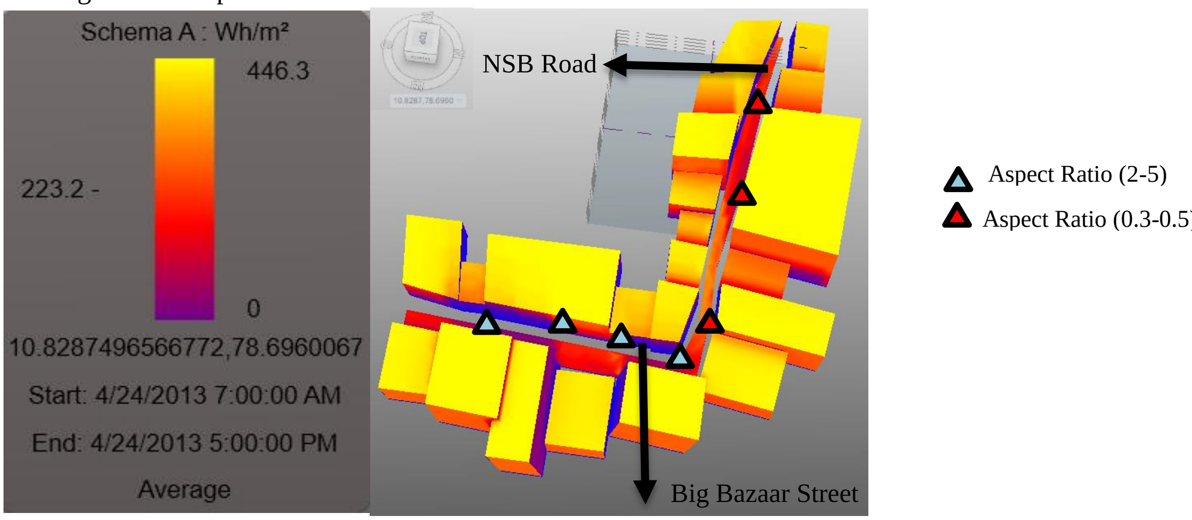

Figure 7: Shows the solar irradiation value of surfaces in NSB Road and Big Bazaar Street. (Simulated Using Autodesk VASARI)

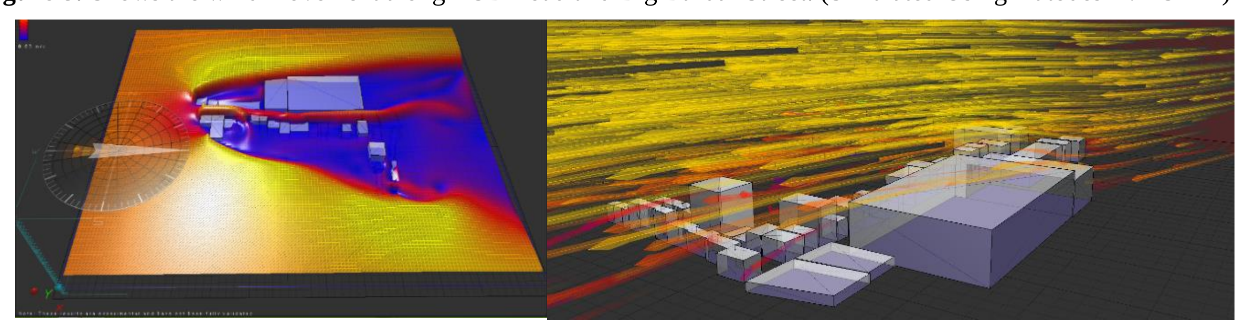
- The open space between the buildings in the Urban Canyons along the East - West orientation streets experienced more radiation on the base surface (roads) compared to that of the vertical surfaces (building façade). This phenomenon was opposite in the urban canyons of the North - South orientation. (**Figure 7**).
- The urban canyons with Aspect Ratios (2 – 5) in both the NSB Road and the Big Bazaar Street had air temperature values less compared to that of the urban canyons with Aspect ratios (0.3 – 0.5). But when the PET (Physiological Equivalent temperature) values were calculated using RAYMAN software for the five different time periods, the values were above the normal comfort range. The PET values (22° C min. - 43° C max), which is much above than the normal range of comfort. (When the comfort range for Tiruchirappalli City was calculated using the weather tool of Ecotect 2011 the range was found to be 26° C - 31° C). The reason behind this discomfort range even in canyons with more aspect ratio is because of very poor wind speed (range between 0.27m/s – 0.54 m/s) due to the high density. When the study area was simulated using the Autodesk Vasari software it was found that practically no wind movement at the height of 2.8m from the ground surface, which is almost the height of the space used by the pedestrians **(Figure 8).**

Figure 8: Shows the wind movement along NSB Road and Big Bazaar Street. (Simulated Using Autodesk VASARI)



- Since Tiruchirappalli belongs to hot humid climatic zone, the problem of humidity was also felt in certain canyons with poor wind movement. Increased air temperature (almost 42° C) and humidity as high as 63% further deteriorated the outdoor comfort condition of the pedestrian users.
- Autodesk Vasari, Ecotect and RAYMAN were all validated with the questionnaire survey. The Percentage of people Dissatisfied were more in NSB Road (East - West) compared to the users of Big Bazaar Street (North – South) for all the five time period **(Figure 9)**.

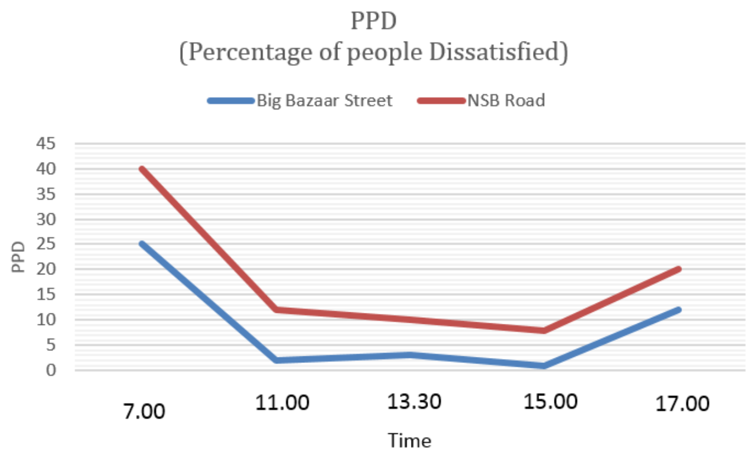


Figure 9: Shows the PPD value for NSB Road and Big Bazaar Street

Design Best Practice Methods

After careful study and analysis of the urban canyon and urban microclimate interactions following design best practice methods were derived **(Figure 10):**

- The choice of building material used on the surface of all planes of urban elements (Base plane – floor, Vertical Plane – walls, Overhead Plane – Building Projections) should be more environment friendly, in radiating heat.
- The street orientation has to be considered while deciding on the material choice for roads. (In the case of NSB road maximum radiation was from the asphalt used on road).
- As how the built space - open space ratios are worked out in 2 – D plans of individual building designs, similar structure has to be considered for the city planning to enable and enhance wind movement. But in areas of high density and high rise buildings like the study area (CBD), outdoor microclimate can be resolved only by providing shading, as wind movement is restricted.
- In order to enhance wind movement among high density built spaces, regulations can be formulated to design buildings with solid and void volumes.

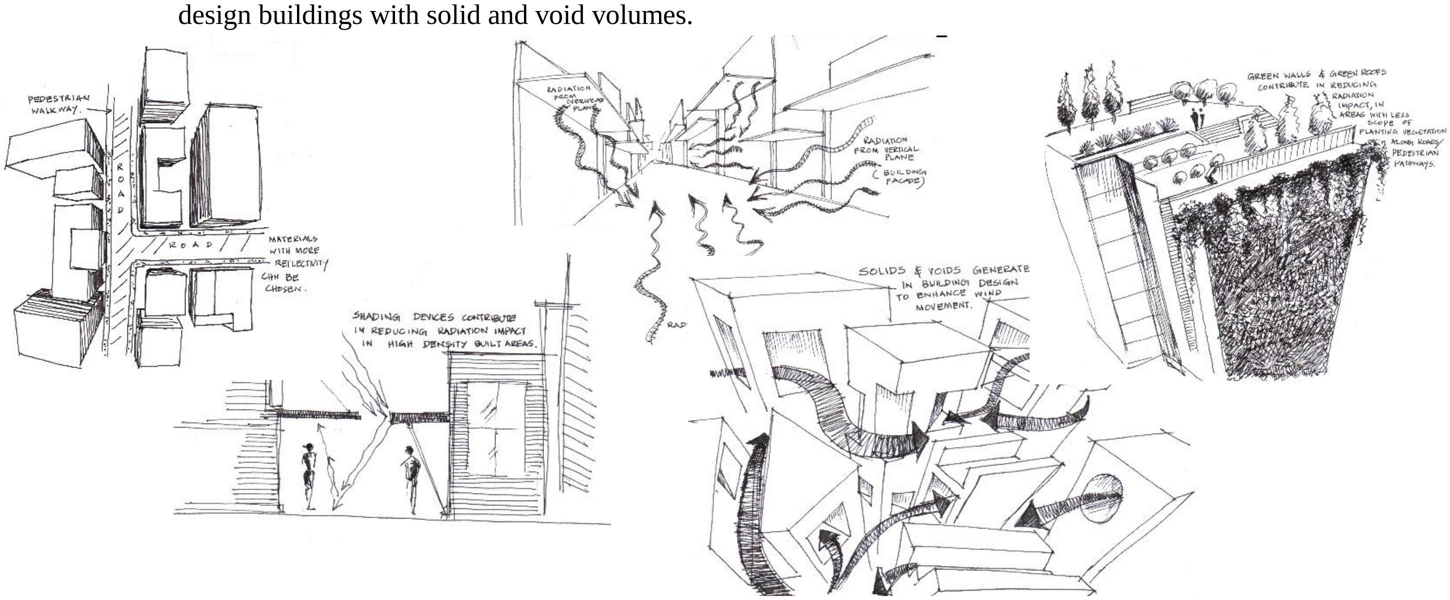

Figure 10: Design best practice methods

- The planning of cities should also consider the 3 - D of the built volumes, since aspects like SVF can be resolved. The canyons can be designed with surface projections and overhanging to reduce the impact of surface radiation of the materials as well they can provide shading for the pedestrian users.
- Since there is less scope of vegetating spaces near buildings , greening of roofs and walls can be done to minimize the impact of radiation.

Conclusion

In a Tropical country like India, where more activity is extended outdoors, climatic comfort of pedestrians is inevitable in the design of urban spaces. Though there are many climatic factors that control urban microclimate, the most important of them is the air temperature, since it directly influences the PET (Physiological Equivalent Temperature). From the study of the commercial streets in the Tiruchirappalli city it was obvious that the air temperature value can be controlled with the help of canyon geometry as well as by enhancing the movement of wind. The increase in wind also offers important role in minimizing the impact of excess humidity in air. These design best practice methods has to be executed right from the level of individual building design to the scale of city design in coherence with the climatic factors. Because the physical factors of the urban canyon and the city climatic factors mutually interact and influence one other. This influence has to be made positive to achieve better comfort condition for the urban pedestrian user.

ABSTRACT

Located in Nottingham, the BASF house serves as an example for energy efficiency and affordability. The house incorporates a number of passive and active measures to allow thermal comfort for residents. The success of these passive strategies appears to be supported by energy simulation studies. However, before establishing confidence in the results attained by energy simulations, it is critical to understand that energy modelers rely on simulation software to predict building energy performance. Despite the maturity of current energy simulation tools, they are inadequate to make precise predictions for the obvious reasons that local conditions, physical parameters, and usage scenarios are not fully known. As a consequence, passive design measures may fail to achieve their expected benefits. Indeed, models may show predictions that deviate from what we would observe in the realized building. The primary cause of such deviation is uncertainties in the model parameters and formulations. The important question to be raised is whether the recognition of the performance gap between design and reality would lead us to rethink the applicability of passive design measures. This paper focuses on analyzing the impact of those uncertainties on the evaluation of passive design measures in the BASF house. The exploration focuses on the risk that a passive design solution may cause unacceptable discomfort, which could potentially lead to its rejection despite its initial selection based on the results of a conventional energy simulation. This level of understanding is essential if we are to make rational design decisions regarding the applicability of passive strategies.

INTRODUCTION

In 2007, BASF, a German chemical company devoted to energy efficiency and resource protection, initiated a project to design, construct, and test modern methods of construction in six innovative, flexible houses. The first to be completed was the BASF house, located in Nottingham, England. Built in wet, cold weather, the house contains both active and passive strategies, the latter of which play a crucial role in establishing thermal comfort of residents.

Passive Strategies

Passive design arises with the desire to maximize thermal and environmental benefits. Building designers need to thoroughly investigate the thermal characteristics of building components and systems to determine the optimal solution to minimizing heat loss in the winter and heat gain in the summer. Although a purely "passive" design without any mechanical intervention is preferable in terms of energy, more often than not, it does not meet the thermal comfort requirements, leading to the creation of hybrid systems, that is, incorporating mechanical devices into passive elements allowing the latter to function appropriately. One example is the BASF house, which combines a range of strategies such as shading, buffer zones, compactness, highly insulated building fabric, and double-glazed windows, as well as phase-change materials on the ceiling, an earth-air heat exchanger for cooling and pre-heating air, and natural ventilation in order to achieve desired performance.

Earth-Air Heat Exchanger

Earth air heat exchangers, buried to moderate depths, are generally underground horizontal ducts or pipes in which outside fresh air or re-circulated air is conditioned by the thermal mass of the earth and channeled into the house. To enhance heat transfer, pipes are usually made of polypropylene.

Phase-Change Materials

Because of their high storage density and latent heat property, phase-change materials are critical in the thermal energy storage of the building envelope system. One of the potential applications for phase-change materials is to incorporate them into the envelope system in buildings for energy conservation. During the summer, benefits include a time shift in the thermal load during the day and thus a decrease in the peak temperature. Since they will help reduce cooling loads by absorbing heat during the day and recycling it during the night, it is hypothesized that phase-change materials will work efficiently in the climate of Nottingham with warm days and cold nights.

A METHODOLOGY FOR EVALUATIING PASSIVE MEASURES UNDER UNCERTAINTY

To evaluate the performance of passive strategies, designers base their decisions on energy simulation results to predict building behavior after implementation. However, when predicting the performance of buildings, current building performance assessment tools do not account for risks that can lead to designers' having false confidence about the expected performance of sustainable measures and an impression about the likely underperformance of passive houses in reality. Mlakar and Strancar (2011), and Rodrigues and Gillott (2011) showed problems of overheating in passive houses during operation in the summer with in-situ measurements. Furthermore, Larsen and Jensen (2011) acknowledged that possible problems with high indoor temperatures are not anticipated during the design process via simulations but observed after the building is finished at the site. These findings motivate us in proposing a methodology for evaluating passive design measures with a clear indication of the risks of indoor discomfort. Additional risk information will infuse confidence about the effectiveness of proposed design measures for improving the thermal comfort of a passive house.

The probability that an unfavorable event will occur is referred to as "risk." To measure risk, one must analyze the indefinite nature of the outcome of a situation, or uncertainty. Such is the case in predicting building performance, which entails two main sources of uncertainty. The first is uncertainty related to the physical properties of building components, system parameters, and operational scenarios. For example, the performance of building HVAC systems generally deviates from their nameplate efficiency, which stems from industrial compliance tests. Instead, their on-site performance may vary, depending on the local environments and construction and installation circumstances such as the effect of bad workmanship. Another source of uncertainty is the reliability of the model itself. Current most state-of-the-art energy simulation tools represent complex physical processes in reality through certain levels of abstraction and simplification. In addition, the modeler has to make assumptions resulting from a lack of information or expertise, which can lead to an overstatement of performance. In reality, no model can capture all aspects of a system and predict its full spectrum of performance during operation. The need to translate the identified uncertainties to risks has called for a type of uncertainty analysis that quantifies the impact of physical parameter uncertainties, modeler assumptions, and model simplifications on the outcomes. Such an analysis is typically carried out using a Monte Carlo approach with an appropriate sampling technique in order to increase computational efficiency. The Monte Carlo (MC) simulation uses random number generators to model stochastic event occurrences.

de Wit and Augenbroe (2002) and MacDonald (2002) introduced a general procedure for uncertainty analysis of building thermal performance. Khazaii (2012) studied different sources of HVAC system uncertainty such as equipment manufacture tolerance, system degradation, and duct leakage. Wang, Augenbroe and Sun (2014) quantified the impact of realization uncertainty of construction detailing and workmanship on building energy performance. Their studies showed that a quantitative uncertainty assessment is essential in a design decision making process. These efforts represent only a small slice of a growing body of work that studies the effect of uncertainties encountered at various model levels (e.g., micro-climate, building level, and system level). Referring to the above sources, this paper uses the parameter uncertainty quantifications and techniques.

This paper casts new light on the evaluation of passive design strategies, which will explicitly show risks associated with design decisions. It will provide designers with quantitative evidence that certain levels of building performance will be accomplished or not. In this study, we propagate uncertainties through GURA-W (Georgia Tech Uncertainty and Risk Analysis Workbench) (Lee, Sun, Augenbroe and Paredis 2013). The probability distributions of uncertainty parameters are contained in an XML repository and sampled with Latin hypercube sampling. We then feed these uncertainty parameters into an EnergyPlus simulation engine. Eventually, the simulation results will show the performance of passive design strategies and their associated risks. The following sections present a case study showcasing the validity and value of our proposed methodology.

BASF HOUSE AND MODEL ASSUMPTIONS

The BASF house has an area of about 100 m^2 divided into ground and first floors as depicted in Figure 1. The ground floor mainly consists of an open-plan living room and a kitchen with a staircase connected to the first floor, allowing natural ventilation from the stack effect. The first floor comprises of two main southern bedrooms and a smaller one on the north (unoccupied). The house has a fully glazed double-height southern sunspace with external shading and internal adjustable blinds. Openings are carefully placed around the house, facilitating optimal use of natural cooling in the summer.

Figure 1. the BASF house

In terms of construction methods, ground floor walls are made of insulated concrete formwork (ICF) while the first floor walls and the roof are constructed of structural insulated panels (SIPs). In total, 100 m^2 of PCM boards that store and release heat from the living room, bedrooms, and the sunspace are sandwiched between plasterboards and oriented strand boards (OSB). Windows and curtain walls are double glazed and filled with argon with a U-value of 1.66W/m^2K. The interface between multiple construction methods eliminates easily avoidable thermal bridges. In addition, the air permeability of the house is addressed by incremental pressurization tests and vulnerable area treatment, so the final house is among the most airtight in the United Kingdom (3.38m^3/h/m^2 at 50 Pa). An earth air heat exchanger containing 36m of piping buried at a depth of 1.5m supplies 0.05 m^3/s of precooled or preheated air to the sunspace from 11am to 5pm and to the living room from 12pm to 2pm.

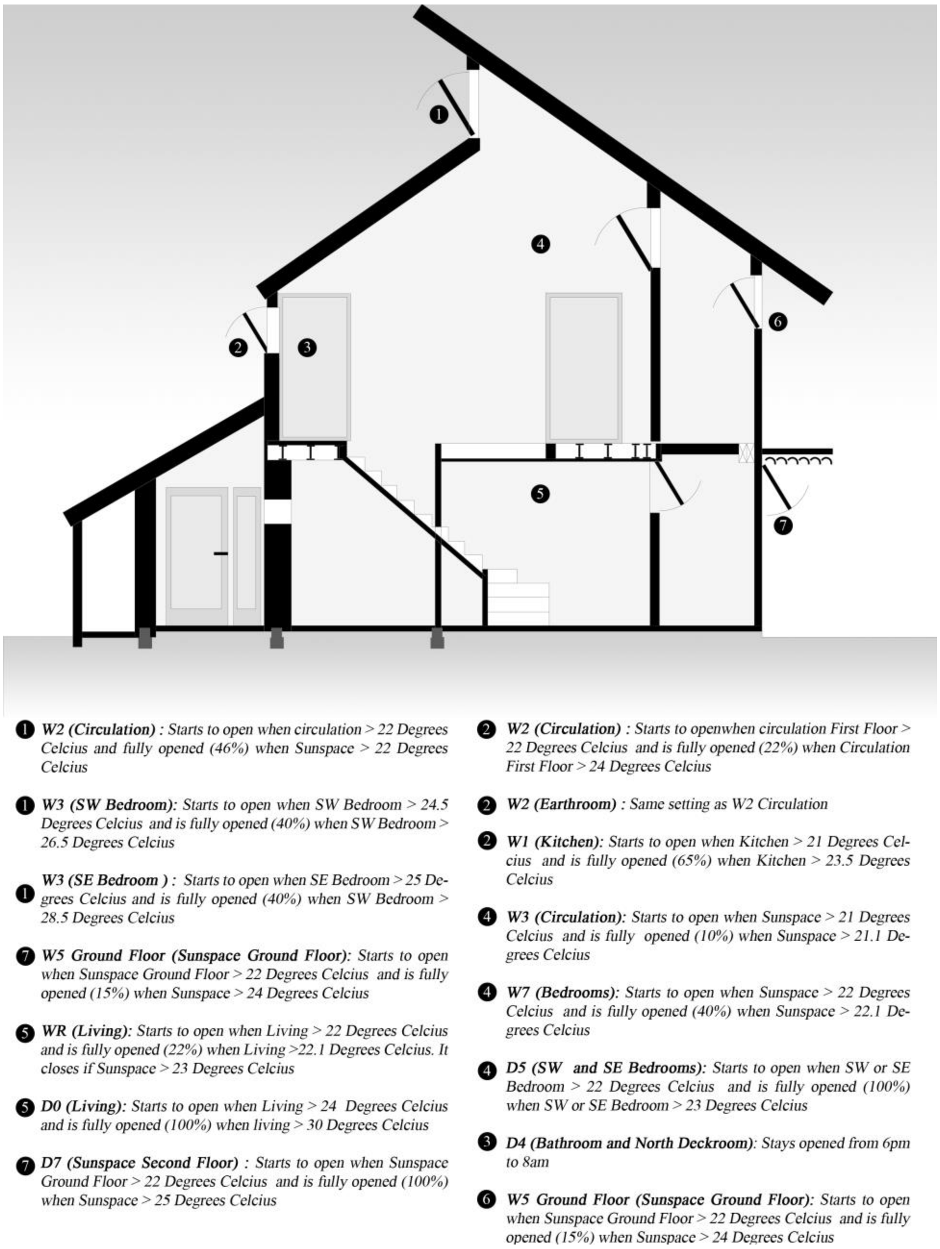

Figure 2. Ventilation strategy in the BASF house

The development of thermal models requires a series of further assumptions. Information on construction types, occupancy schedules, and internal heat gains are loyal to the design intention and onsite implementation. PCM boards are simulated using the conduction finite difference solution algorithm in EnergyPlus, which uses an implicit finite difference scheme coupled with an enthalpy-temperature function to account for phase-change energy accurately. The local soil type is assumed to be standard (density 1800kg/m^3, conductivity 1.45W/mK, and thermal diffusivity 6.015×10^{-7}m^2/s) in the calculation of the average temperature, the amplitude and the phase constant of the soil surface. Then the performance of the earth-air heat exchanger is determined given these boundary conditions. Figure 2 showcases the ventilation strategy. More information about the BASF house can be found in Rodrigues (2010).

RE-EVALUATION OF MEASURES IN THE BASF HOUSE

Following the previous reasoning, risks associated with passive design strategies cannot be thoroughly understood without acknowledging the uncertainties. Uncertainty analysis can provide information with respect to whether investigated strategies can meet the comfort requirement with a specific degree of confidence, for instance expressed as a discomfort risk tolerance such as the allowed probability that the number of discomfort hours is exceeded. Rodrigues and Gillott (2011) compared deterministic simulation results with actual measurements for the BASF house and concluded that the simulation results are similar to the actual measurements except that the former over-predict the overheating issue in the sunspace and underestimate it in the north bedroom. The recorded observations seem to strengthen our argument that relying totally on deterministic results may give rise to false confidence and be insufficient in supporting design decision making. Therefore, the proposed design measures for the BASF house must be reevaluated under uncertainty. As an example, this study analyzes the risk of overheating in July, when the peak temperature might occur in Nottingham.

Risk of Overheating

According to CIBSE, the benchmark for overheating is 26°C in the living room and 25°C in the bedroom. If the benchmark is exceeded, the duration of the time above 28°C in the living room and 26°C in the bedroom should be no longer than 1%. Therefore, we first take the percentage of occupied time (12am to 9am, 5pm to 12am on weekdays; all the time on weekends) outside the above comfort zone as the performance indicator to evaluate the risk of overheating in the BASF house. Another way to rate discomfort is the absolute number of hours that a certain threshold is exceeded during a given critical month. The following results can be easily translated to the absolute number of hours in July by realizing that 1% corresponds to 5 to 6 hours. It should be noted that in order to identify if certain measures could fail the comfort tolerance of future occupants, a risk conscious measure will have to be established. If, for the sake of the argument, we assume that the risk tolerance of the occupants is that in the southwest bedroom in July, the probability that the number of discomfort hours above 28°C exceeds 35 (or 6% of the occupied time) cannot be higher than 8%, we would see that the current design would be acceptable based on Figures 3a and 3b. Figure 3a shows the distribution of the number of hours in July, when the temperature in the southwest bedroom exceeds 28°C during occupied hours. The predicted range is the combined effect of the uncertainties mentioned above. In Figure 3b, the error bar represents the 90 percent confidence interval of the quantity of interest. For example, for the southwest bedroom, the bar chart suggests with 90% confidence that the percentage of time during which the indoor temperature is higher than 25°C will be between 16.3% and 26% with a median value of 20.6%. The measurement data from Rodrigues and Gillott (2011) are in close agreement with the confidence interval predicted through our uncertainty analysis, confirming the validity of our model.

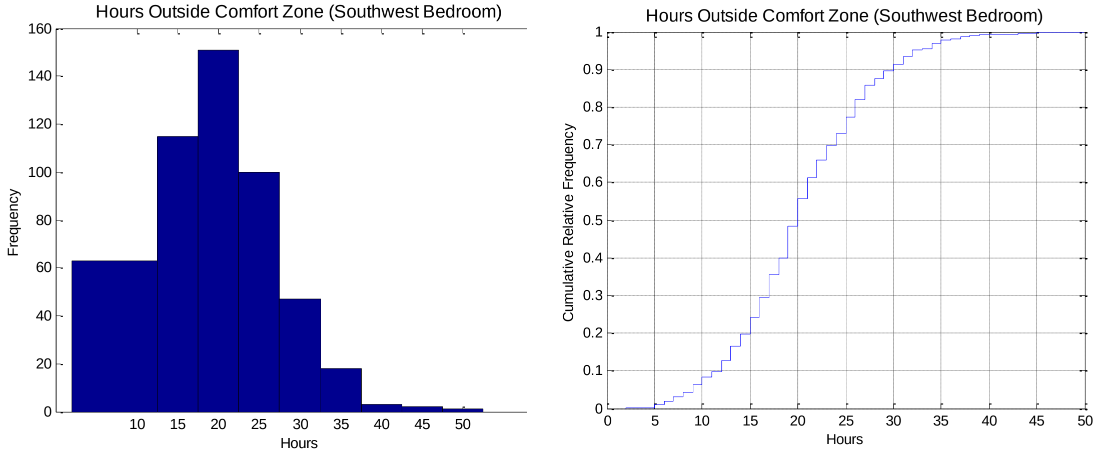

Figure 3a. Histogram (left) and cumulative relative frequency (right) of hours of discomfort in July

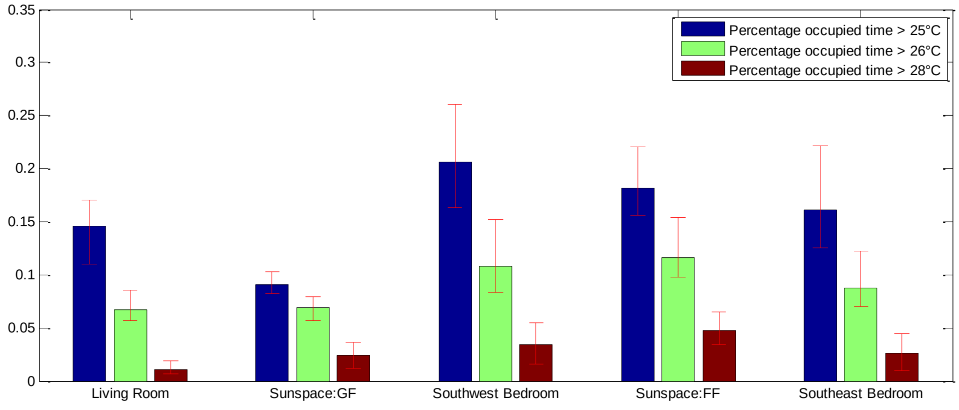

Figure 3b. Percentage of time outside the comfort zone with a 90% confidence interval (base case) in July

Effectiveness of EAHE

Since the EAHE ventilates only the living room/kitchen area and the sunspace on the ground floor and because the benefits of natural ventilation in the bedrooms through open doors have not been proven, this section simulates the model developed previously without including the EAHE module to validate its effect. The EAHE supplies 0.05 m^3/s of precooled or preheated air, which translates to 0.68

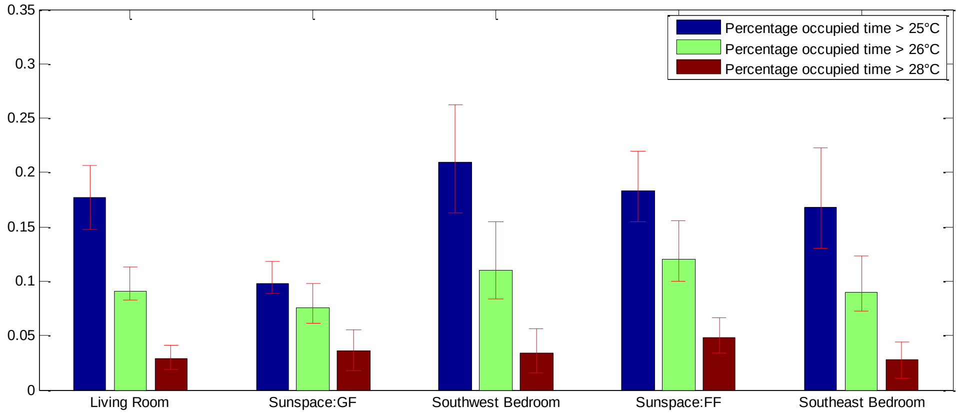

Figure 4. Percentage of time outside comfort zone with 90% confidence interval (no EAHE) in July

ACH for the living room/kitchen areas and 2.6 ACH for the ground floor sunspace. As the results show (Figure 4), these two areas benefit most from the EAHE air supply: While the percentage of time exceeding the comfortable temperature of 25°C in the living room increases from 11% ~ 17% to 14.8% ~ 20.7% without the EAHE, that in the sunspace increases only slightly from 8% ~ 10.3% to 9% to 11.8%. Only a minor impact on the rest of the house suggests the intended air movement by design might need a more sophisticated fluid dynamics model to guide and validate it.

Effectiveness of PCM Boards

Rodrigues and Gillott (2011) observed that PCM boards are not below their phase-changing zone long enough to completely release the heat they absorb on a daily basis, which may undermine their effectiveness. Their work in TAS for the BASF house is incapable of simulating the effect of the PCM boards, leaving several hypotheses unproven.

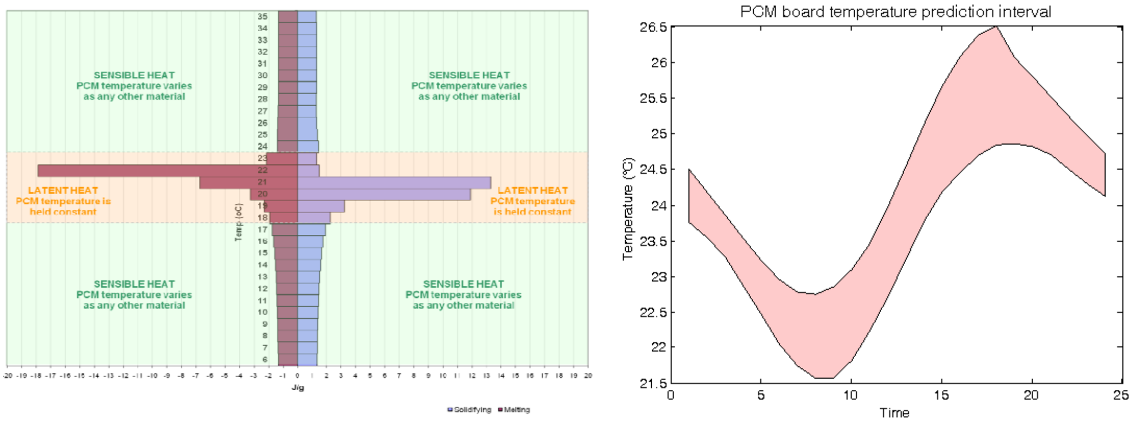

Figure 5. Properties of PCM boards (left) and the prediction intervals of their temperatures (right)

According to the product specs from Rodrigues (2010), the operating temperature of the Micronal Knauf SmartBoard 23 is between 19°C to 23°C, and the maximum enthalpy slope is at 20°C. Figure 5 shows the prediction interval of the temperatures of the PCM boards in the living room on July 1. For example, their minimum temperature (around 8am) could be somewhere between 21.6°C to 22.8°C instead of a deterministic value. Unfortunately, PCM boards exceed their phase-changing temperature most of the time without major solid-liquid transitions. Therefore, they are not very effective in absorbing excessive heat from the room. Our finding supports the original argument by Rodrigues and Gillott (2011).

Exploring Ventilation Strategies

In this section, we test how the previous outcome is sensitive to the ventilation strategy presented in Figure 2 to account for another layer of uncertainty resulting from occupancy and use. We confine the ventilation air exchange rate per hour for each room as no larger than 15 for exterior spaces and 10 with adjacent spaces, which mimics the window/door closing behavior of users in case of undesirable effects such as a draft. Compared to the results in Figure 2, those in Figure 6 show only minor differences. However, for the southwest bedroom, the risk tolerance of occupants is exceeded: the probability that there are more than 35 occupied hours that the temperature exceeds 28°C is higher than 8%. We could conclude from the variability of outcome that the current design given the more realistic ventilation strategy would be unacceptable assuming the above risk tolerance of occupants.

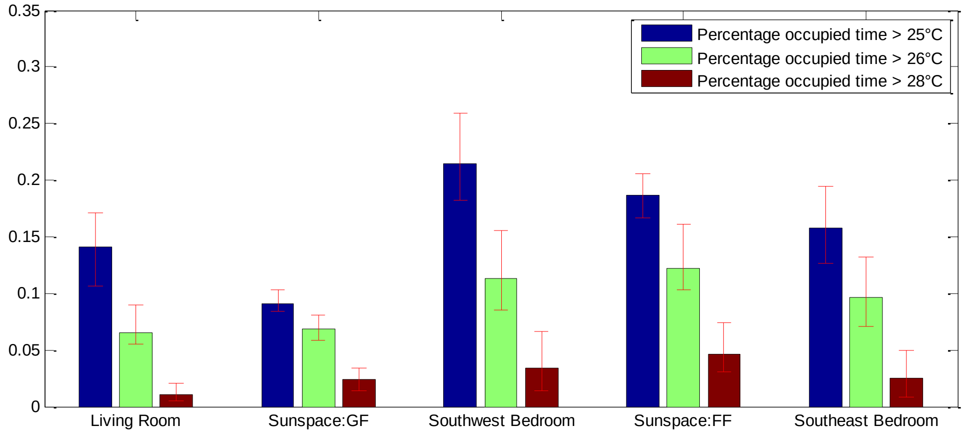

Figure 6. Percentage of time outside the comfort zone with a 90% confidence interval (ventilation)

CONCLUSION

The contribution of this paper is that we have proposed a methodology for evaluating the effectiveness of passive design strategies under uncertainty. Given the risk tolerance of the intended occupants of the building, this methodology enables risk conscious design for clearly identified risk measures. Although the analysis in the study was confined to the BASF house, the proposed method has generality to guide future practice. We simulated passive measures in the BASF house and inferred the variability of uncertainty parameters from previously published work. The dynamic energy simulations led to the following conclusions:

(1) Our proposed methodology excels in the following ways: It is able to predict the probability of the occurrence of extreme conditions inside buildings such as overheating while the conventional simulation approach cannot; the merit of different design options could be assessed against an occupant specific discomfort tolerance which will lead to superior decision making on which measures improve on the current design and which do not. We have demonstrated this point by showing that for a reasonably chosen, explicitly defined discomfort risk tolerance of an occupant, the BASF house would be deemed unacceptable. Such outcomes would have necessitated the BASF design to undergo additional measures that reduce the risk to fall within the tolerable range.

(2) In terms of the earth-air heat exchanger, with the current limited operation time, it does not address the problem of overheating in the bedrooms although the comfort level in the living/kitchen area improved: The occupied time period when the temperature was higher than 25°C declined by 17% on a median level. The PCM boards did not contribute significantly to maintaining indoor comfort during the summer because of the lack of sufficient natural cooling to discharge stored heat. Thus, we recommend that designers have a good sense of the operating temperature range before choosing a specific product. In addition, we found the ventilation strategy an important piece of our jigsaw puzzle of maintaining a desirable indoor environment with passive measures. Even when the exterior condition is appropriate for natural cooling, the fact that an over-ventilated space with drafts could be as uncomfortable as an overheated one, may deem some passive designs unacceptable after all. Discomfort from drafts can be assessed with an uncertainty analysis of the airflows using a CFD model, which could be a topic of future work.

1.0 ABSTRACT

Energy use of a building can be derived from five sources: Embodied Energy from mining and manufacturing of materials, Energy from transportation of materials, Energy from construction of the building, Energy use during operation of the building, and Energy used in the disposal of the building at the end of its life. Buildings use many materials with a high Embodied Energy, and it is estimated that, 10% of its total energy use comes from Embodied Energy in materials. Thus, the use of low Embodied Energy Materials for the sustainable development is preferred. Life cycle assessment (LCA) offers a comprehensive approach to evaluating and improving the environmental impacts of buildings materials, buildings and its products through all of its life stages.

Brick and Cement are majorly used materials in building industry. Kiln Burnt Brick is majorly use exterior wall material in the market. Also, Aerated Concrete (AAC) is a non-combustible, cementitious building material that is expanding into new worldwide markets.

The Paper will be aimed to compare the environmental impact of materials- Kiln Burnt Brick and Autoclaved Aerated Concrete used for wall assemblies. Study will be focused on evaluating the materials with respect to its Embodied Energy, Energy and Resource consumption, Environmental Impact in terms of CO2 Emissions, Cost, Health safety etc. The functional unit and unit distance will be defined to allow comparisons to be made between materials. The study will include interaction with the Manufacturers, Market study of the materials, and use of material in a particular building. The final objective of the paper is to evaluate the materials on the bases of Life Cycle Assessment Impact Categories which includes: Raw Material Index (RMI), Water consumption, Embodied Energy (EE) and Operational Energy (U-Value), Electricity, Occupational Health and Safety (OHS Index), Total Cost, CO2 Emissions.

Key words: - Life Cycle Assessment, Materials, Kiln Burnt Brick, Autoclaved Aerated Concrete, Life Cycle Assessment Impact Categories.

2.0 INTRODUCTION

Building construction in India is estimated to grow at a rate of 6.6% per year between 2005 and 2030 (McKinsey and Company, 2009). The building stock is expected to multiply five times during this period, resulting in a continuous increase in demand for building materials, which could have long lasting implications in terms of natural resource depletion, future energy demand, local pollution, contributions to greenhouse gas emissions as well as socio-economic conditions of a significant number of low-income workers. Thus it is an imperative and urgent need to have a comprehensive plan for development of walling materials production in India, with the least impact to the earth.

Ar. Neha Bhatia is an Asst.professor in the Department of Architecture, Accredited to Pune University, Pune, Maharastra.

All materials have environmental implications. Thus the choice of materials for a project requires considerations of aesthetic appeal, initial and ongoing costs, life cycle assessment considerations (such as material performance, availability and impact on the environment) and the ability to reuse, recycle or dispose of the material at the end of its life. It is estimated that, 10% of buildings total energy use comes from embodied energy in materials. Thus, the use of low embodied energy materials for the sustainable development is preferred. Life Cycle Assessment (LCA) offers a comprehensive approach to evaluating and improving the environmental impacts of buildings materials, buildings and its products through all of its life stages from cradle-to-grave (i.e., from raw material extraction through materials processing, manufacture, distribution, use, repair and maintenance, and disposal or recycling).

Brick and Cement are majorly used materials in building industry. Kiln Burnt Brick is majorly use exterior wall material in the market. Also, Aerated Concrete (AAC) is a non-combustible, cementitious building material that is expanding into new worldwide markets.

3.0 AIM AND OBJECTIVE

The Paper is aimed to compare the environmental impact of materials- Kiln Burnt Brick and Autoclaved Aerated Concrete used for wall assemblies.

The final objective of the paper is to evaluate the materials on the bases of Life Cycle Assessment Impact Categories which includes: Raw Material Index (RMI), Water consumption, Embodied Energy (EE) and Operational Energy (U-Value), Electricity, Occupational Health and Safety (OHS Index), Total Cost, CO2 Emissions.

4.0 METHODOLOGY

In this assessment the tools of Life Cycle Assessment are integrated, which includes due consideration of all life cycle stages fixed in the ISO 14040 –14043 standards: Goal and Scope Definition, Life Cycle Inventory Analysis, Life Cycle Impact Assessment and Life Cycle Interpretation.

Life Cycle Inventory Analysis includes assembling data and analyzing it on a suitable system boundary. Life Cycle Impact Assessment is the evaluation of the material and energy flows raised in the inventory analysis according to certain environmental effects.

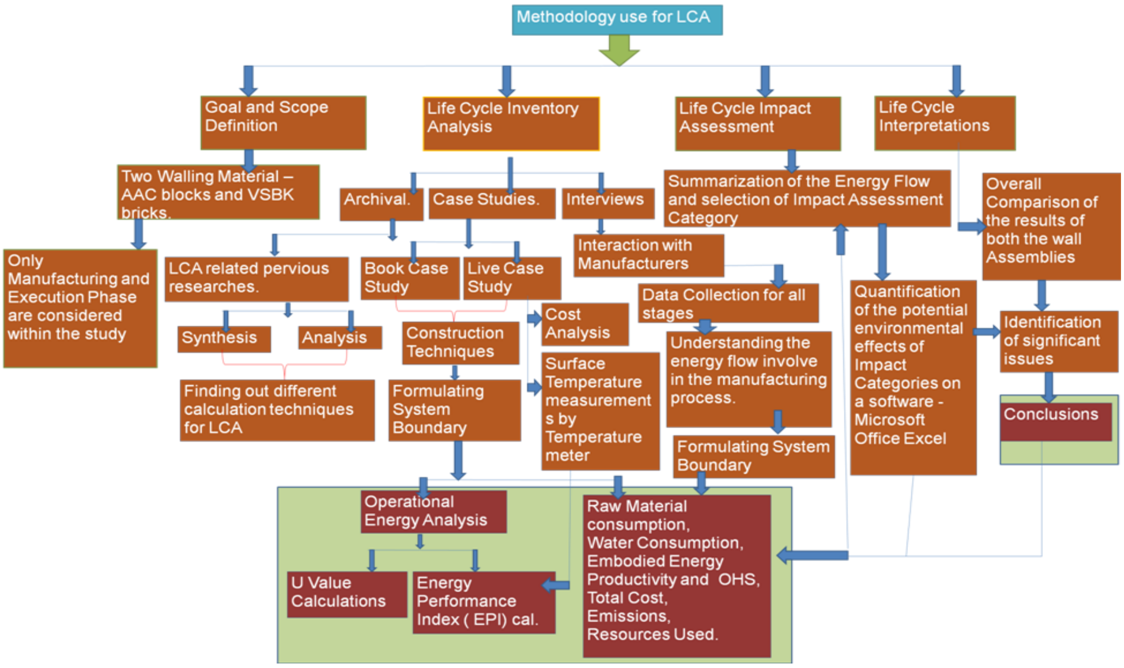

Figure 1 *Methodology use for Life Cycle Assessment.*

Thenafter, Impact Assessment categories are selected, which includes: Raw Material Index (RMI), Water Consumption, Embodied Energy (EE) and Operational Energy (U-Value), Electricity and other Resources, Occupational Health and Safety (OHS Index), Total Cost, CO2 Emissions. Life Cycle Interpretation consists of Identification of significant issues, evaluation and conclusions.

5.0 SCOPE AND LIMITATION

Study is focused on evaluating only two walling materials - Kiln Burnt Brick and Autoclaved Aerated Concrete with respect to its formulated Impact Assessment Categories. The functional unit and unit distance is defined to allow comparisons to be made between materials. The study includes interaction with the Manufacturers, Market study of the materials, and use of material in a particular building.

Building use: Evaluation of the materials and energy consumptions is restricted to the use of a building only, its maintenance and restoring, not considered within this study. Also, Transport of the wastes generated during the Construction and Demolition phase, not considered within this study. No consideration of labour cost as it will have negligible effect on the results.

To understand the implication of these materials, the live site data collection is limited to pune (moderate climate), but to understand the impact of operational energy a theoretically comparative study base has been done with a case study of composite climate.

6.0 LIFE CYCLE ASSESSMENT

A Life Cycle Assessment (LCA) provides a mechanism for systematically evaluating the inputs, outputs and the potential environmental impacts linked to a product or process throughout its life cycle. (ISO 14040). LCA addresses the impacts of a product through all of its life stages.

Life Cycle Assessment is a technique to assess environmental impacts associated with all the stages of a product's life from cradle to grave.

6.1 EMBODIED ENERGY

Embodied energy is the total energy required for the extraction, processing, manufacture and delivery of building materials to the building site. Energy consumption produces CO2, which contributes to greenhouse gas emissions, so embodied energy is considered an indicator of the overall environmental impact of building materials and systems. It does not include the operation or disposal of materials.

The total amount of embodied energy may account for 20% of the building's energy use, so reducing embodied energy can significantly reduce the overall environmental impact of the building.

Energy consumption during manufacturing can give an approximate indication of the environmental impact of the material, and for most building materials, the major environmental impacts occur during the initial processes.

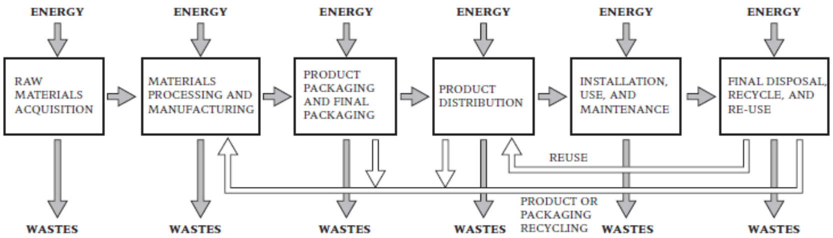

Figure 2 *Typical phases of materials Life Cycle, along with inputs and outputs at each phase.*

7.0 LIFE CYCLE INVENTORYANALYSIS OF AAC BLOCKS AND VSBK BRICK

7.1 Autoclaved Aerated concrete and Vertical Shaft Brick Kiln (VSBK)

AAC is lightweight, precast building material that simultaneously provides structure, insulations, and fire & mold resistance. Main ingredients include fly ash, water, quicklime, cement, aluminium powder & gypsum. The block hardness is being achieved by cement strength, & instant curing mechanism by autoclaving. Gypsum acts as a long term strength gainer. The chemical reaction due to the aluminium paste provides AAC its distinct porous structure, lightness & insulation properties, completely different compare to other lightweight materials.

The VSBK is a vertical kiln with a stationary fire and a moving brick arrangement. The figure below shows the VSBK principle in a schematic diagram. The kiln operates like a counter current heat exchanger, with the heat transfer taking place between the air moving upwards and the bricks moving downwards.

9.0 LIVE CASE STUDY (CLIMATE: MODERATE)

9.1 Park Turquoise (Location: Wakad, Pune)

Turquoise is Apartment Flats of 2 bhk (1150 sq. ft), 2.5 bhk (1330 sq. ft), 3 bhk (1550 sq .ft).
A Park Turquoise is the luxurious 70-acre township boasting of ample landscaped and open areas.

(a)

(b)

Figure 7 *(a) Layout of Live Case Study (b) Typical Floor Plan of the Building.*

9.2 Construction Techniques

The building envelope has used Autoclaved Aerated concrete blocks instead of conventional bricks. The windows are glazed units with low thermal transmittance. Building Envelop is of AAC blocks with external 1:4 cement and sand plaster and internal gypsum plaster.

U-value calculations for 150mm and 200 mm AAC wall=0.76 w/km² degC and 0.61 w/km² degC.

U-value calculations for 150mm and 230 mm VSBK wall = 1.95 w/km² degC and 1.77 w/km² degC

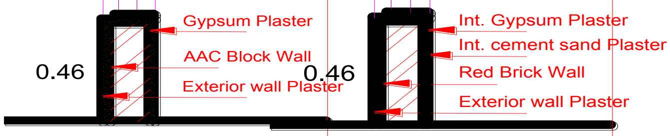

Figure 8 *AAC block Wall Section* *Brick Wall Section*

9.3 Cost Analysis of the Project

All required quantities are refered based on the data collected from the Live Case Study to allow comparision between the two materials.

			Aerated Autoclaved Concrete Blocks				Burnt Red Brick

The total emission factor for electricity is 16.43g CO2 / MJ.
About 0.098 tonnes of CO2 are produced per gigajoule of embodied energy = 0.098Kg of CO2 per MJ of embodied energy.

Figure 15 *Resources used in wall assemblies /cu mt.*

11.0 LIFE CYCLE INTERPRETATIONS

11.1 Overall Comparision

1. It is apparent that masonry units with the least or no clay content (i.e AAC bloc which contains waste material such as Fly Ash) have low impact. Density also influences raw material impact, thus AAC blocks resulting from the aerated nature (approximately 80% air) have lower raw material impact. Larger block size reduces the quantity of mortar wastage on construction site. Additionally, the raw materials that are consumed are generally abundant and found in most geographic regions, allowing them to be locally sourced. Furthermore, much of the raw materials used in AAC production may consist of recycled materials, including copper mine tailings and flyash, a byproduct of coal-fired power plants.

2. AAC blocks use cement in the production process and require curing. However, steam curing under high pressure (autoclaving) results in significantly lower water consumption. Larger block size reduces the quantity of mortar used in construction and thus the water requirement on site. Whereas, Water requires for curing Brick Masonry for 7 days is much large, thus the water consumption increases.

3. Burnt bricks show much higher embodied energy compared to AAC Blocks. The thermal performance of AAC wall assembly is also generally superior to Burnt bricks as reflected in the U-values. AAC blocks wall assembly have the lower U-value due to the porous nature of the material.

4. Burnt brick production is traditionally a labour intensive process. The use of manual labour for moulding therefore results in significantly lower productivity compared to mechanized processes.

Block size also influences construction productivity and a larger block size requires less time and effort for construction. Poor conditions for labour at brick kiln sites are reflected in OHS index compared to AAC. Units producing AAC Blocks are generally located close to large urban areas and do not require labour to live on site during the production period as in the case of Burnt Brick.

5. Cost of AAC block is higher but the overall cost of the construction reduces drastically. Due to the larger block size of AAC masonry reduces the mortar quantity contributing to lower cost for the wall assembly. Also due to its lightweight characteristics the steel consumption reduces by 0.4kg which lower the total cost of construction.

6. CO2 emissions are lower for AAC Production and Wall Assembly compared to Burnt brick Walls and its production.Also, Resource Consunmtion of AAC is lower and thus the CO2 emmissions.

ACKNOWLEDGEMENT

I would like to thank people of AAC block production company Anjali Ventures Ltd., Surat.

ABSTRACT

Straw bale use in buildings may be an interesting way to decrease our energy needs and our impact on environment. The present paper describes an experimental set up to monitor three straw bale buildings recently built in Belgium. For each building, results on temperature and relative humidity, inside and outside, are analyzed, as well as internal evolution of temperature and humidity distribution in the walls. The first building is an office building where two finishing are compared. Measurements also provide additional data on CO_2 levels and electric consumption. The two other buildings are dwellings where live one single family. In the first one, a wall in the bedroom and a retaining wall are analyzed. In the second one, a wall in the bedroom and a wall in the bathroom are analyzed. Their hygrothermal behavior is discussed based on simulation results obtained with WUFI Pro and WUFI Plus software. The criterion for the validation of wall behavior is based on water content distribution through the walls. The paper confirms the great potential of this type of building technology and helps to identify how to assess and validate their effective hygrothermal behavior.

Key words: *Straw bale, field measurements, whole building simulation, water content criterion*

INTRODUCTION

Straw bale building techniques are evolving since the XIXth century. Some techniques are still evolving and prefabrication of entire walls has started in Belgium since few years. The present paper presents results based on an experimental setup installed in three straw bale buildings in Belgium. For each of these cases, the straw bale walls were prefabricated in the same factory with the same building technique, except small variations. The wall is built with 46 cm or 36 cm of straw (structured with a timer framed structure), covered on the inside with an 4cm earth plaster and on the outside with a 1.6 cm bracing panel (open to vapor). This walls typology was presented in [Evrard et al., 2012].

The first building is a small office building (approx. 80m²) built in a large industrial hall in Franière. It is thus protected from rain and direct sun. The walls are built with 46 cm of straw. Preliminary simulation results were presented in [Evrard, 2013]. As the building is occupied since September 2013, almost 9 months of monitoring can be analyzed.

The second building is a family house (approx. 225 m²). The monitoring also started in September 2013, but because of undesired power supply failure, only less than 5 months of data can be analyzed. Two different walls are compared, both built with 46 cm of straw. One is facing west and inside environment is a bedroom; the other is a retaining wall in the entrance hall.

The third building is also a family house (approx. 120 m²) built in an urban context in Uccle. It has an attached house on one side. The monitoring started in November 2013 and around 7 months of measurements were thus analyzed. The walls are built with 36 cm of straw in this case. As in the other house, two different walls are compared. One is facing north and inside environment is a bathroom; the other is facing south and inside environment is a bedroom.

METHODOLOGY

The main objective of the monitoring setup presented in this paper is to enable the calibration of numerical simulations and to validate the performances of straw bale walls. It was thus necessary to gather complete climate data for each building (having a different location). For the three buildings, outside temperature and humidity was measured. Sun radiation was measured for the two family houses (west for the first one and south for the second one). Rain load was only measured for west wall in Tongrinne (second building). In addition, temperature and humidity of inside environment of the three buildings was measured, as well as temperature and humidity at different places through the wall. In this first building, complementary sensors were installed to measure CO_2 concentration, windows and doors openings, as well as a webcam to be able to assess occupation. Electrical consumption of monitored room is also measured.

All measures of temperature and humidity were made with the sensors Sensirion SHT75 (except surface temperature made with PT100). A special tube containing a chain of sensors was developed to monitor the temperature and humidity inside the wall, at specific positions. In the two first buildings, 5 sensors are respectively positioned at 2cm (under earth plaster), 11cm (first quarter in straw), 22cm (middle position in straw), 33cm (last quarter in straw) and 44cm (under bracing panel) from inside surface. In the last building, two chains of sensors were used, each with 4 sensors, respectively positioned at 2cm (under earth plaster), 11cm (first third in straw), 22cm (second third in straw) and 33cm (under bracing panel) and at 1cm, 12cm, 23cm and 34cm from inside surface. CO_2 concentration is measured with Gascard NG (3000ppm) sensor. All sensors are connected to a data logger Campbell CR1000 and sent by Internet on a dedicated sever. The data are processed with Microsoft Excel software to allow their use and comparison with numerical simulations. Simulations at wall level are achieved with WUFI Pro 5.2 software and WUFI Plus 2.1 software was used at the building level.

RESULTS

Building n°1: Small office building in Franière

Two different earth plasters on inside surface are compared. For each plaster, three chains of sensors were installed (high, medium and low height). Temperature and humidity evolution are similar for all of these cases, only small variation were observed. Temperature under inner plaster follows very closely the temperature of inside air, and temperature under the bracing panel follows approximately the temperature of outside air (in the hall). The difference is due to the thermal inertia of earth plaster (discussed in [Evrard, 2013]).

As shown in Figure 1 (left), outside temperature (in the hall) was almost never under 0°C. Inside temperature of monitored room falls sometimes under 12°C (6 times between end of November and beginning of February) and do not reach 20°C every working days even if the company installed three simple halogen lamp (400W) to heat the building (one in monitored room) end of November. The lamps are turned on in the morning (between 6am and 9am) and turn off at the end of the day (between 6pm and 8pm). As Figure 1 (right) shows, the occupancy is not regular and, sometimes, nobody is working in the office (i.e. end of December).

Figure 2 (left) presents the data collected in the straw bale for the wall with the plaster n°2, at an approximate height of 1m50 (medium height). It shows the evolution of relative humidity at the most humid point of the wall in winter, i.e. 1cm under the outer bracing panel, as well as the evolution of relative humidity at the driest point of the straw bale in winter, i.e. just under inner earth plaster. It appears that the relative humidity is always under 86% under the bracing panel. According to the sorption curve of straw bales measured in the laboratory, at this humidity, water content is around 16% of mass. Results obtained for plaster n°1 are relevant in this paper. Despite current regulation, no ventilation was installed. Figure 2 (right) shows the evolution of CO_2 concentration in monitored room.

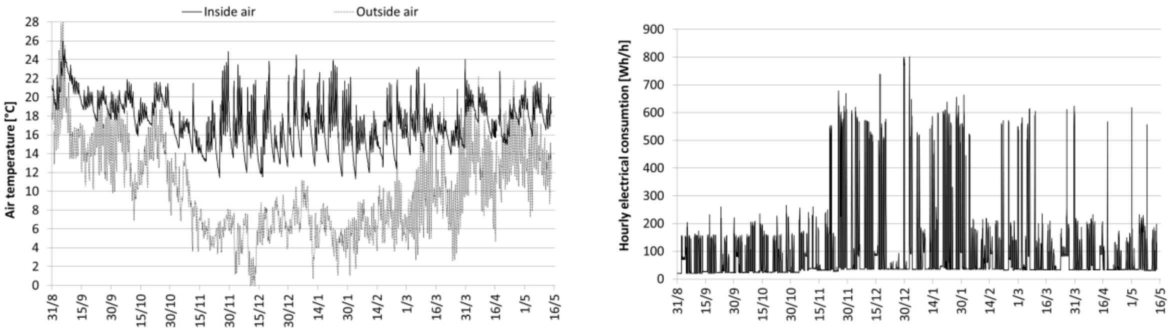

Figure 1 (left) inside and outside air temperature of monitored room in Franière (right) electric consumption of monitored room in Franière.

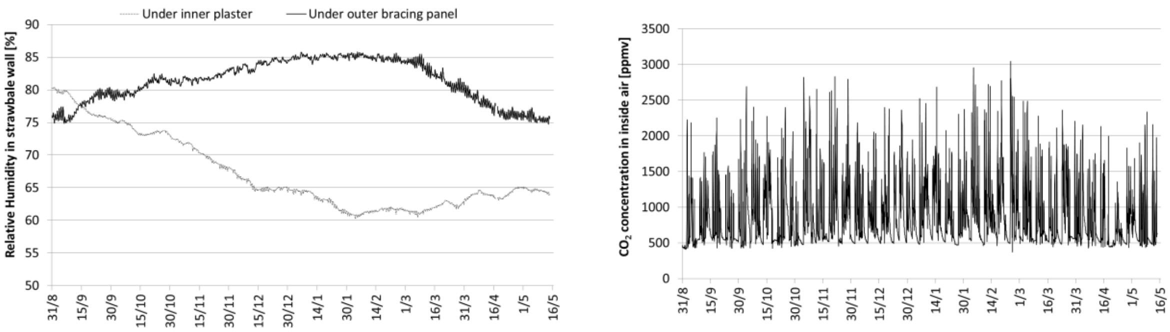

Figure 2 (left) relative humidity under inner plaster and under outer bracing panel of the wall with plaster n°2 in monitored room in Franière (right) CO_2 concentration of inside air in monitored room in Franière.

Building n°2: Family house in Tongrinne

The monitoring of this building started in September 2013, but because of undesired power supply failure, only less than 5 months of data can be analyzed. Two different walls are compared, both built with 46 cm of straw. One is facing west and inside environment is a bedroom; the other is a retaining wall in the entrance hall.

West wall is submitted to driving rain. A water-repellent render system (board, mineral under layer and finishing) was applied on outer surface. Figure 3 shows cumulative rain quantity and sun radiation for this wall, as well as relative humidity through the straw bale.

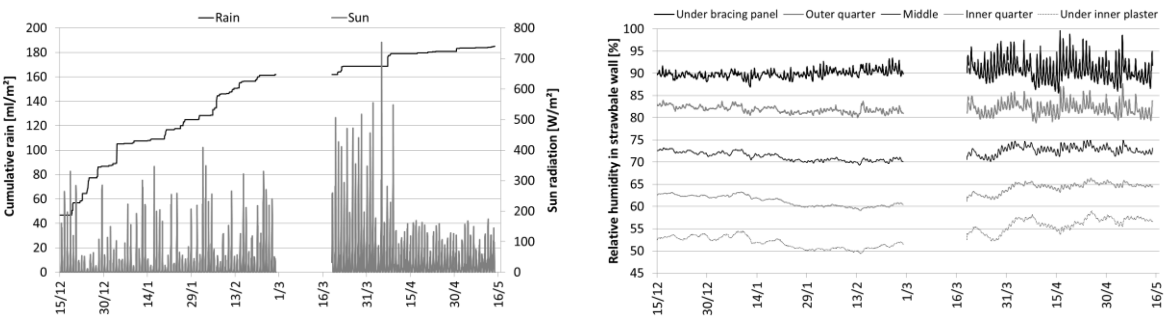

Figure 3 (left) cumulative rain quantity and sun radiation of vertical west wall surface in Tongrinne (right) relative humidity through the straw bale of west wall monitored in Tongrinne.

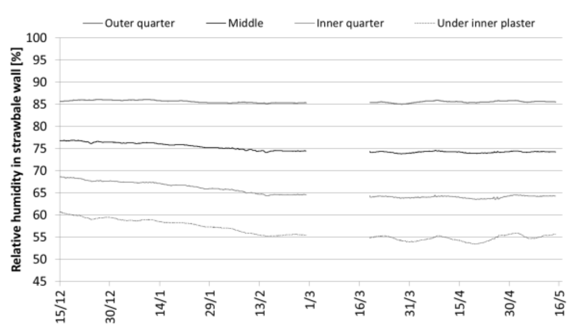
The other wall monitored in Building n°2 is a retaining wall. Inside environment is the entrance hall of the house. Outside environment is in the earth. A water barrier was installed again outer bracing panel, avoiding water to penetrate the wall, but preventing also vapor to transfer out of the wall on this side. Figure 4 (left) shows relative humidity through the straw bale in this wall (the sensor under the bracing panel do not send any information).



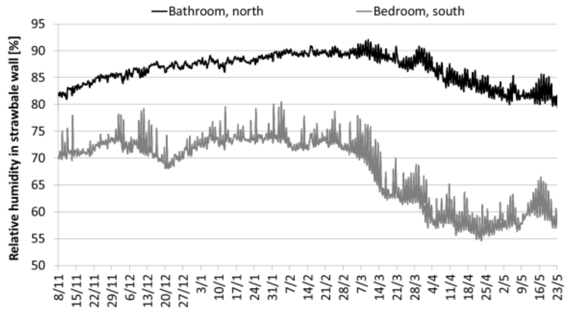


Figure 4 (left) relative humidity through the straw bale of retaining wall monitored in Tongrinne (right) relative humidity under bracing panel of north wall in the bathroom and south wall in the bedroom in Uccle.

Building n°3: Family house in Uccle

The monitoring of this family house started in November 2013 and around 7 months of measurements could thus be analyzed. As in previous house, two different walls are compared, both built with only 36 cm of straw in this case. The first wall is facing north and inside environment is a bathroom; the other is facing south and inside environment is a bedroom. Figure 4 (right) shows relative humidity under bracing panel (the most humid position in the walls) for both walls.

DISCUSSION

Building n°1: Small office building in Franière

Outside temperature and relative humidity from measurements, as well as heating input of electric power released in the room, where used as input in a WUFI Plus simulation (hygrothermal building zone analysis). All necessary material data were gathered during previous step of aPROpaille research. Main parameters are presented in [Evrard, 2013] (exterior wall type “S”). Occupation profile (one man working from 9am to 6pm on week days, with a break between 1pm and 2pm) did not take into account the lightings and the computer, as they are considered in the heating input of the room. Other inputs of the simulation represent real conditions of the unventilated office. A natural ventilation through door and window of 1vol/h between 9am and 10am and between 1pm and 2pm is considered together with a constant infiltration rate of 0.024 vol/h (equivalent to n_{50} = 0.6 vol/h, even if there was no blower door test). This case is thus similar to case S-2 of preliminary simulations presented in [Evrard, 2013].

As illustrated in Figure 5 (left), inside temperature resulting from simulation follows the same trend that measured values. Daily maximum temperature is quite close, but minimum temperature (i.e. after each week-end) is lower in reality. This difference can be due to the hypothesis on ventilation rate and occupation profile. The company should install an adapted heating system to reach comfortable temperature during working days.

Figure 5 (right) shows the evolution of relative humidity at the most humid point of the straw bale in winter, i.e. 1cm under the outer bracing panel, as well as the evolution of relative humidity at the driest point in the straw bale in winter, i.e. just under inner earth plaster. There is a sensible difference between measurements and simulation results in terms of relative humidity in the straw bale. Simulated relative humidity in the straw bale follows the same trend; however, the maximum value under the bracing panel and minimum value under inner plaster are respectively 5% higher and 5% lower in the simulation. This rather small difference is not further analyzed in this paper. As a matter of fact, the relative humidity is always under 90% under the bracing panel. At this humidity, water content of the straw bale is under 20% of mass. According to [Wihan, 2007], no decomposition will occur under a water content of 25% in mass and a degradation of 0,009% a day appears when water content of straw is between 25% and 39% of mass. This analysis depends on the sorption curve of the straw bale and on organic decomposition rate (the values may depend on the density of the straw bale, the type of plant…).

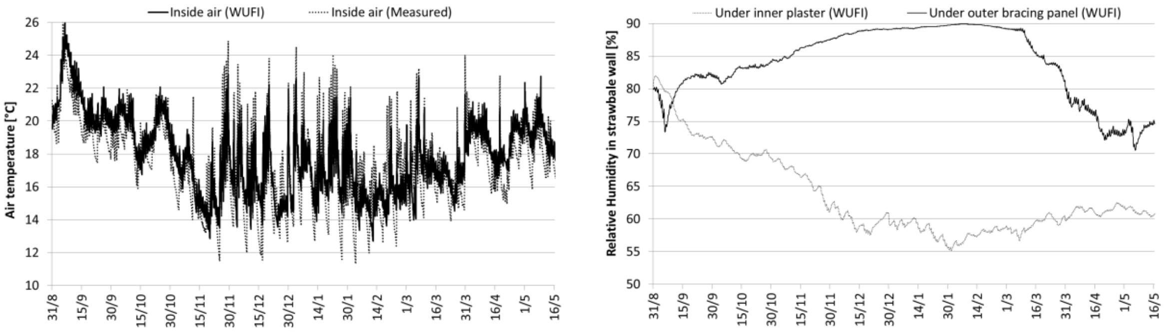

Figure 5 (left) inside air temperature in Franière, simulated with WUFI Plus software (right) relative humidity under inner plaster and under outer bracing panel in the straw bale with plaster n°2 in Franière, simulated with WUFI Plus software.

One last remark can be made on the evolution of CO_2 concentration in the simulation. As we defined a constant occupation every week-days (with a break at noon) and almost no ventilation, CO_2 concentration rises every week-days until around 3700ppmv (vs. maximum value measured is 3000ppmv). A ventilation system (around 30m³/pers) can be used to reduce CO_2 concentration under 1000ppmv (Belgian regulation NBN EN 1377-2007). A precise occupation profile could be assessed based on measured CO_2 concentration, but this goes beyond the scope of this paper because it would need, in addition, a complementary analysis of ventilation rate.

Building n°2: Familly house in Tongrinne

Outside and inside temperature and humidity, as well as sun exposure and rain load on west wall were used to run WUFI Pro simulations (1D hygrothermal analysis). Missing data between the 28th of February and the 19th of March were filled with data measured between the 7th of February and the 26th of February for continuity of the climate file. Material data were gathered in previous step of the research (see [Evrard, 2013]).

For the water-repellent render system, density, thermal conductivity and vapor diffusion resistance factor of each layer were collected from producers. Other parameters (porosity, specific heat capacity, sorption curve…) correspond to a "Cement Plaster" in WUFI database, except liquid absorption coefficient (A-value). Finishing mattering is announced to be "water repellent" and A-value is set to 0.0017 kg/m²s$^{-1/2}$. The producer indicates that sd-value of this layer is higher than 0.5m. As layer must be minimum 1mm in WUFI Pro, the vapor diffusion resistance factor of this layer is set to μ=500 (500*0.001m=0.5m). A-value of the board and render are set to 0.0083 kg/m²s$^{-1/2}$ corresponding to the worst value in class II of standard NF EN 1062-1 (W2 announcer by producer).

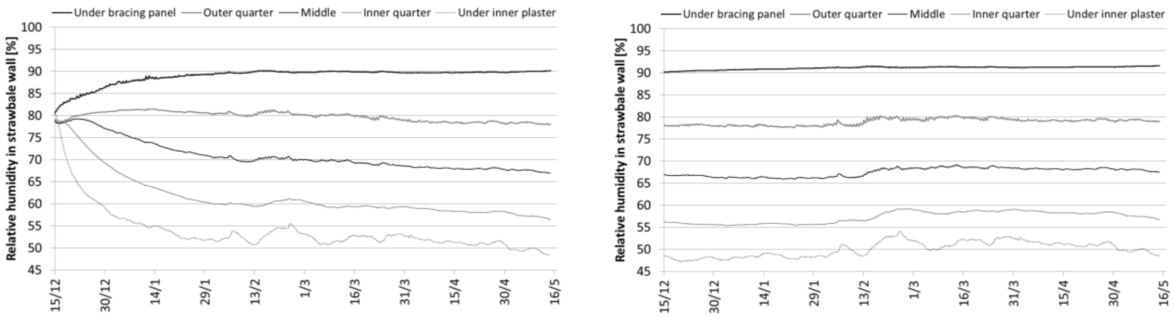

Figure 6 (left) relative humidity through the straw bale wall orientated to the west in Tongrinne (first period), simulated with WUFI Pro software (right) relative humidity through the straw bale wall orientated to the west in Tongrinne (second period), simulated with WUFI Pro software.

Figure 6 (left) shows the simulated relative humidity through the straw bale wall of the west wall in Tongrinne. Initial humidity of the straw bale was set to 80% (constant through component). The two first months are thus very different form measured value, but from the 15th February until 15th of May, the results are in very good agreement. The main difference is the higher daily amplitude of the variations of relative humidity (especially close to outside) in the measurements, but average values are similar.

Measured values are very often over 91.4% of relative humidity, corresponding to a water content over 25% in mass. Simulated values rise until 90% of relative humidity and seem to continue to rises as time passes. A second period (with the same climate file) was simulated starting with water content profile obtained at the end of the first period (which was rather rainy). Figure 6 (right) shows that an accumulation of humidity can be observed. The maximum water content during second period is over 25% of mass. An explanation of this problematic behavior is the rather high vapor permeability of finishing layer (sd = 0.5m or more). If this layer has a sd-value of 0.05m, the simulation shows no moisture accumulation and relative humidity under the bracing panel stays under 90%.

A this point, it has to be noticed, that equivalent simulations, using “test reference year” (TRY) in Uccle (50 km from Tongrinne) for outside climate and EN15026 standard for inside, do not reveal any problem in the wall. The relative humidity of the straw under the bracing panel gets close to 90% but decrease after the month of June. No accumulation is observed and no degradation should occur. It is thus too early to conclude that organic degradation will occur in the straw over time as a significant decrease of relative humidity at this specific place may be observed in following months (summer period).

To simulate the retaining wall, only inside climate was used as an input for simulation. For outside climate (in the earth), a sinus variation of temperature around 15°C and with amplitude of 3°C (maximum on the 1st of August) and a constant humidity of 99% are chosen. No absorption of water is allowed in the wall and a 1mm layer with very low vapor permeability is considered (sd=1500m). As in previous simulation, initial humidity of the straw bale was set to 80% (constant through component). Figure 7 (left) shows that there is a difference of around 5% of relative humidity between simulated results and measurements at the end of the first period. Under the bracing panel, the relative humidity seems to decrease after the 15th of April (the sensor at this position does not send any information). At the opposite, relative humidity under inner plaster seems to increase after end of March. When repeating simulating a second period, starting with water content profile obtained at the end of the first period, a significant decrease in straw bale humidity can be observed, as shown in Figure 7 (right). The results are similar when using a usual inside climate (“normal moisture load”) based on standard EN15026 with TRY reference climate in Uccle (50km from Tongrinne): the maximum relative humidity under the bracing panel during the third year is 83% (86% with “high moisture load”), with no accumulation. Before drawing any conclusion, positive results from simulations suggest to wait to have a longer measuring period to further discuss measured values.

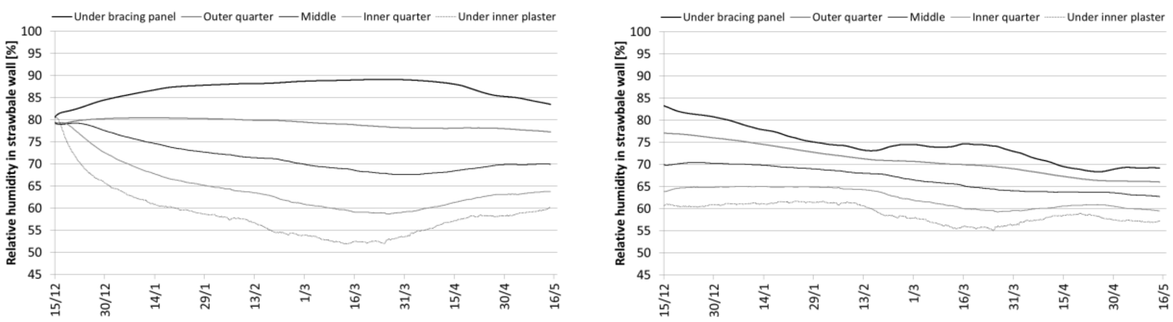

Figure 7 (left) relative humidity through the straw bale retaining wall in Tongrinne (first period), simulated with WUFI Pro software (right) relative humidity through the straw bale retaining wall in Tongrinne (second period), simulated with WUFI Pro software.

Building n°3: Familly house in Uccle

Outside and inside temperature and humidity (in both rooms), as well as sun exposure on south wall were used to run WUFI Pro simulations (1D hygrothermal analysis). Material data were gathered in previous step of the research (see [Evrard, 2013]). A render on outside surface (2cm) was applied on both walls on a wood-cement board (2.5cm) fixed on a wood structure (unventilated air layer of 3cm) directly on bracing panel. The total complementary sd-value of those three layers is supposed to be around 30cm. Rain absorption of outside surface is neglected in the simulations (no rain load was measured in Uccle and the render is supposed to be water-repellent). Inner finnishing is also neglected for both walls (thin lime plaster).

Figure 8 shows that there is a significant difference of relative humidity under the bracing panel between measurements and simulation results. In the bedroom, simulation results are 10% to 15% higher during the two first months and after four month. In the bathroom, results are similar at the beginning and at the end of the period, but diverge between the second and the seventh months (difference up to 15%). At this point, these simulation results cannot be used because they may not be relevant. This might be due to hypothesis on rain, or on material parameters (outside render and inner plaster). Further research is needed. However, it has to be noticed that measured values are fine in the bedroom (relative humidity of the straw under the bracing panel is always under 80%) and, for the bathroom, they exceed 91.4% of relative humidity under the bracing panel, only during few days.

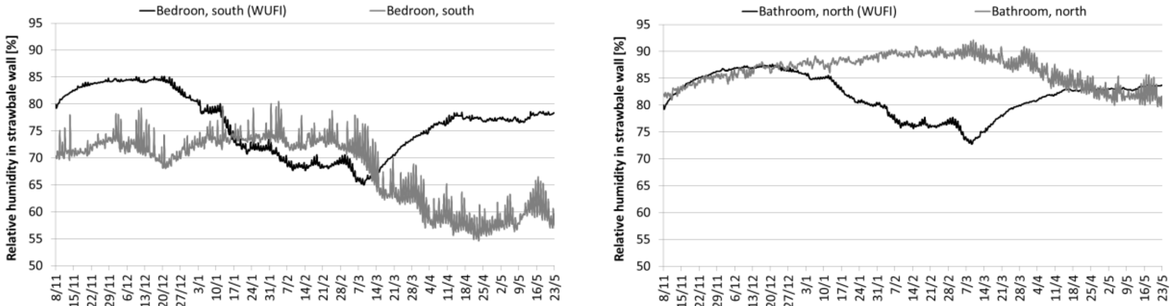

Figure 8 (left) relative humidity under bracing panel of south wall in the bedroom in Uccle, simulated with WUFI Plus software (right) relative humidity under bracing panel of north wall in the bathroom in Uccle, simulated with WUFI Plus software.

CONCLUSION

The paper presents the first analysis of the data collected in three straw bale buildings in Belgium: one office and two family houses. All data are collected on a dedicated server and are analyzed after a processing with Microsoft Excel software. Based on [Wihan, 2007] and [Evrard et al., 2012], validation of wall behavior focusses on the humidity in the straw bale. Relative humidity of straw should not exceed 91.4% (corresponding to a water content of 25% of mass). The most humid place in the walls (if no undesired source of humidity exists), is located few centimeters under the outer bracing panel. Results at this place are discussed based on simulation results, either with WUFI Pro (using indoor and outdoor climate from field measurements) or with WUFI Plus software (when data on occupation and heating load are also available).

The office building in Franière (Building n°1) was built in an industrial hall and is not submitted to rain or sun. Therefore, the analysis of occupation and heat load was simplified. All data were analyzed with WUFI Plus software. The behavior of all walls was validated (no decomposition will occur). A relatively good agreement between measured relative humidity and simulation results were observed (i.e. less than 5%). Inside temperature from simulation follows the same trend as measured values, but do not decrease as fast at night and during the week-end. Additional research on occupation profile and ventilation rate should help to calibrated more precisely the simulations (e.g. in terms of CO2 concentration of inside environment).

In Tongrinne (Building n°2), west wall seems to have a problematic behavior as the relative humidity in the straw under the bracing panel is often higher than 91.4%. In addition, simulation results indicate that the wall may have a moisture accumulation problem. However, other simulations using test reference year (TRY) in Belgium did not confirm this result, and a new analysis of monitored data should take place after summer period. This uncertainty may come from unknown material parameters of outer render added on prefabricated straw bale walls.

The second wall in Tonginne is a retaining wall. Unfortunately, one sensor (under bracing panel) does not send any data. The simulation is rather positive as it shows that on a longer period, the humidity of the wall should decrease under critical value. A special attention will be given to this wall in the future as it is normally avoid designing retaining wall with straw bales.

In Building n°3 (in Uccle), simulation results did not fit measurements. Again, this could be due to unknown material parameters of outer render added on prefabricated straw bale walls. In addition, west wall is submitted to driving rain, but no rain measurement was implemented in this case. Further analysis of this building is needed to validate hygrothermal behavior of the walls. Nevertheless, measured values are not considered to be critical (only few days over 91.4%) in this case.

If many data can still be not explored, the monitoring implemented in three straw bale buildings can already confirms that it is possible to design and validate straw bale walls based on a single quantified criteria: moisture content of straw few centimeters under the bracing panel. More research is needed to understand the link between critical moisture content and other parameters (density of the straw bale, type of plant, forming process of the bale…).

In the meantime, straw bale walls can be trusted to design high efficiency house and to offer comfortable and sustainable living places.

Microclimatic Effects of Individual Trees with Their Transpiration

Takashi Asawa, PhD

ABSTRACT

This paper quantifies whole-tree transpiration rates for urban tree species using a weighing lysimeter and identifies the microclimatic cooling effect of the individual trees. A novel weighing lysimeter was developed for measuring the whole-tree transpiration rate with a high degree of accuracy. Eleven urban tree species were selected and their whole-tree transpiration rates were measured during the summer season. The daily transpiration amounts of the selected trees, whose heights ranged from 3 m to 7 m, varied from 10 kg to 30 kg under clear skies and water supply conditions. The ratio of the daily transpiration amount to potential evaporation was 0.6 $\pm$ *0.3 when using the standard of crown projection area. The vapor diffusion conductance peak appeared during the morning, and that of transpiration appeared in the afternoon under clear sky conditions. The peak values of transpiration rates for tree species that showed large transpiration amounts were over 3 kg/h. This value is equivalent to more than 2 kW of latent heat flux. The peak values of transpiration rate and vapor diffusion conductance decreased as soil water content decreased, and the latent heat flux decreased from 2 kW to 0.7 kW by the water stress of the tree. This means that the cooling effect decreased to one third. The relationship between vapor diffusion conductance and soil water content was hysteretic when the soil water content was varied by the water-supply stop test. A decrease in vapor diffusion conductance appeared two days after the water supply was terminated, and it recovered three days after water supply resumption.*

INTRODUCTION

In order to understand the microclimatic cooling effects of trees in urban spaces, it is important to quantify their transpiration rates and latent heat fluxes, taking into account species characteristics and soil water content. In previous studies that dealt with the transpiration of trees, transpiration characteristics were reported and compared among different tree species and sizes (Chen et al. 2011; Peters et al. 2010). Whole-tree transpiration rates in these studies were mainly estimated by sap flow measurement using the Granier method (Köstner et al. 1998), or via transpiration measurements for several leaves using the porometer method (DeRocher et al. 1995). However, these methods provide an indirect estimation of whole-tree transpiration, and it has been difficult to obtain accurate whole-tree transpiration rates. Therefore, differences in whole-tree transpiration rates between differing species and tree sizes are uncertain, as is the averaged value of the transpiration rate among tree species in urban environments.

Whole-tree transpiration measurement data are important and useful for assessing the environmental performance of built environments, including urban greening, as well as for the selection of input and validation data for microclimate simulations. In Japan, the Japanese government has

Author A is an associate professor and Author B is a graduate student in the Department of Environmental Science and Technology, Tokyo Institute of Techonlogy, Yokohama, Japan.

promoted the use of CASBEE (Comprehensive Assessment System for Built Environmental Efficiency) (Murakami et al. 2014), which has been developed by the Japan GreenBuild Council (JaGBC) and the Japan Sustainable Building Consortium, for use in building developments by construction companies, design offices, and real-estate developers. CASBEE-HI (Heat Island) is a component of CASBEE, and is focused on the evaluation and promotion of countermeasures that can mitigate the urban heat island effect. In CASBEE-HI, the cooling effect of tree transpiration is simply evaluated using data from forests and trees under different conditions, therefore, the applicability of the data and the reliability of the evaluation criteria have been discussed in both academic fields and in terms of practical use (Teshirogi and Koshimizu 2011). This discussion has been spurred by a lack of reliable and applicable data for urban trees and the above issue is indicative of the importance of measurement data related to whole-tree transpiration.

This paper reports a novel attempt to measure whole-tree transpiration rates for urban tree species by use of a large weighing lysimeter, and compares the transpiration rates and cooling effects among these tree species. In addition, the effect of soil water content on the transpiration rate is examined for *Zelkova serrate* during the summer season. The obtained data will contribute to the creation of a fundamental database for heat island countermeasures using urban trees.

METHODS

Materials and Site

Previous studies of plant physiology have discussed the effects of leaf life-span (evergreen or deciduous), xylem porosity, trunk diameter (sapwood area) and tree height on transpiration characteristics. The leaf life-span correlates with photosynthetic capability and xylem porosity, while trunk diameter and tree height affect the water supply capability to the leaves. In the present study, we selected 11 tree species for the comparison experiment, taking into account leaf life-span (evergreen and deciduous) and xylem porosity. Table 1 shows the selected trees and their characteristics. The tree heights varied from 3 m to 7 m in the year 2012, during which many of the measurements were conducted. These trees were planted in individual large planters with areas of 1 m^2 and depths of 0.6 m.

The measurement site is an experimental field with an area of 8800 m^2 in Miyoshi city of Aichi prefecture, Japan. The positions of the trees are shown in Figure 1 and Figure 2. The distances between the trees were greater than 4 m, so that each tree could easily receive solar radiation and air flow. This planting condition was considered for application of the experimental results to urban environmental conditions.

Measurement devices and methods

Whole-tree Transpiration Rates. In order to accurately measure whole-tree transpiration, weighing lysimeters were developed using weighing load cells (Asawa et al. 2012). Whole-tree transpiration rates were measured by the change in tree weight within the planter. For the long-term measurement of *Zelkova serrate*, a platform weighing machine (Sartorius AG, CAPS4-1500LL-I) was used. The water balance was also measured, including the amount of supply and drainage water. The evaporation from the soil surface was restricted by a cover, and the soil surface was shielded from rain water by a shed. Therefore, the weight change was clearly identified as the transpiration rate. For short-term measurements of the other tree species, S-type load cells (Minebea, U3S1-100K~5T-NS) were used. The planter was suspended by the load cells at three points, and the weight change was measured (Figure 3). In outdoor experiments, wind can be the source of noise and error in weighing measurements. In the previous study, we showed that this method removed the effects of wind by allowing the selection of data recorded when the fluctuation of weight values were small and stable in a short time span, and we confirmed that the measurement error of whole-tree transpiration rates was within 100 g/h when wind velocity was below 1.5 m/s (Asawa et al. 2012).

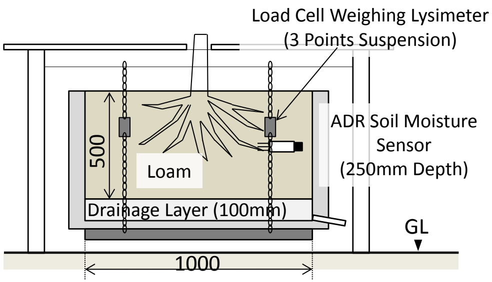

Figure 3. Weighing lysimeter for whole-tree transpiration measurements (Short term measurement)

Table 2. Measurement devices

Precipitation	Tipping bucket type rain gauges TE525MM (Campbell Scientific Inc.)

Meteorological Data and Water Balance. The meteorological data was measured at the northern part of the experimental field. The measurement devices are shown in Table 2. The measurements consisted of global solar radiation, air temperature, relative humidity, three-dimensional wind direction and velocity, and photosynthetic photon flux density. The measurement height for wind direction and velocity was 4 m. Soil water content was measured by an ADR soil moisture sensor with a ThetaProbe. The water supply and water drainage volumes were measured by tipping bucket-type rain gauges. The water supply volume was fully controlled and the water supply was automatically implemented at midnight on each day.

Measurement Periods and Conditions. The transpiration rate of *Zelkova serrate* was measured continuously from July 2010 to the end of 2013. During the water stress test for *Zelkova serrate*, the water supply was stopped for several days. The transpiration rates of the other ten species were measured for about two weeks in the summer of 2012 and 2013, and three species were measured at a time. The results obtained during clear sky days were selected and used for the analysis, so as to select data gathered under identical conditions.

Estimation of Vapor Conductance. The transpiration from a leaf can be described as a vapor diffusion process, and expressed in an equation as the product of vapor pressure deficit and vapor diffusion conductance. The physiological characteristics of transpiration, including stomatal control, find expression in the vapor diffusion conductance. The vapor pressure deficit is the difference between the saturated vapor pressure of the leaf and atmospheric vapor pressure. In this study, whole-tree vapor diffusion conductance is estimated by Eq. (1) using measured whole-tree transpiration rates and vapor pressure deficit. Eq. (2) shows the components of vapor diffusion conductance.

$$G = ET / W \tag{1}$$

$$G = 1 / (r_a + r_s) = g_a \cdot g_s / (g_a + g_s) \tag{2}$$

RESULTS AND DISCUSSION

Comparison of Transpiration Rates among Urban Tree Species

Daily Transpiration Amount. The measured daily transpiration amounts are shown in Table 1. For *Quercus mirsinifolia*, the transpiration rate was measured in both 2012 and 2013, because the tree had been moved from an area enclosed by other trees to an open space before the 2012 measurement. The tree species that showed the largest daily transpiration amounts were *Zelkova serrata* (2010), *Quercus serrata* and *Cinnamomum camphora*, the values of which were approximately 30 kg. The next largest amounts were observed in *Quercus mirsinifolia* (2013), *Quercus acutissima* and *Zelkova serrata* (2012), which showed values of approximately 25 kg. In contrast, the smallest transpiration amounts were observed in *Quercus mirsinifolia* (2012), *Styrax japonica* and *Magnolia sellata*, with these species showing values of approximately 10 kg. The transpiration amounts of *Zelkova serrata* and *Quercus mirsinifolia* largely varied from year to year. Although the leaf area of *Zelkova serrata* increased from 15.4 m^2 in 2010 to 28.9 m^2 in 2012, the transpiration amount slightly decreased. Water conductance in trunks and branches are restricted by the area of the roots and sapwood, therefore, the maximum transpiration value of *Zelkova serrata* was 30 kg/day under the conditions of planter size (1 m × 1 m × 0.6 m) and trunk diameter (0.1 m). In contrast, for *Quercus mirsinifolia*, although the crown shape and leaf area did not change considerably from 2012 to 2013, the transpiration amount increased by a factor of three. These findings indicate that photosynthetic ability largely increased due to the change in tree location from an enclosed space to an open space, which resulted in changes in the surrounding conditions.

Diurnal Changes of transpiration rate and latent heat flux. Figure 4 shows diurnal variations in transpiration rate, vapor diffusion conductance and latent heat flux for 11 tree species. A peak in transpiration rate appeared in the afternoon for tree species that showed large transpiration amounts. In contrast, for trees that displayed small transpiration amounts, the peak appeared in the morning. The peak values for *Zelkova serrata* (2010), Q*uercus mirsinifolia* (2013), *Quercus serrata* and *Cinnamomum camphora* were over 3 kg/h. This value is equivalent to more than 2 kW and 400 W/m^2 of latent heat flux. A peak in transpiration rate for these trees, whose heights ranged from 3 m to 7 m, varied from 1.3 kg to 3.6 kg. These values are equivalent to the range from 880 W to 2400 W for latent heat flux. Therefore the difference in cooling effect was approximately 1500 W between these trees. Peaks in vapor conductance appeared in the morning and the values decreased into the afternoon for all species. This result indicates that the stomata were closed in the afternoon, during which solar radiation and vapor pressure deficit were high, so as to minimize the water deficit. The species with small transpiration amounts were more sensitive to the water deficit than those exhibiting large transpiration amounts.

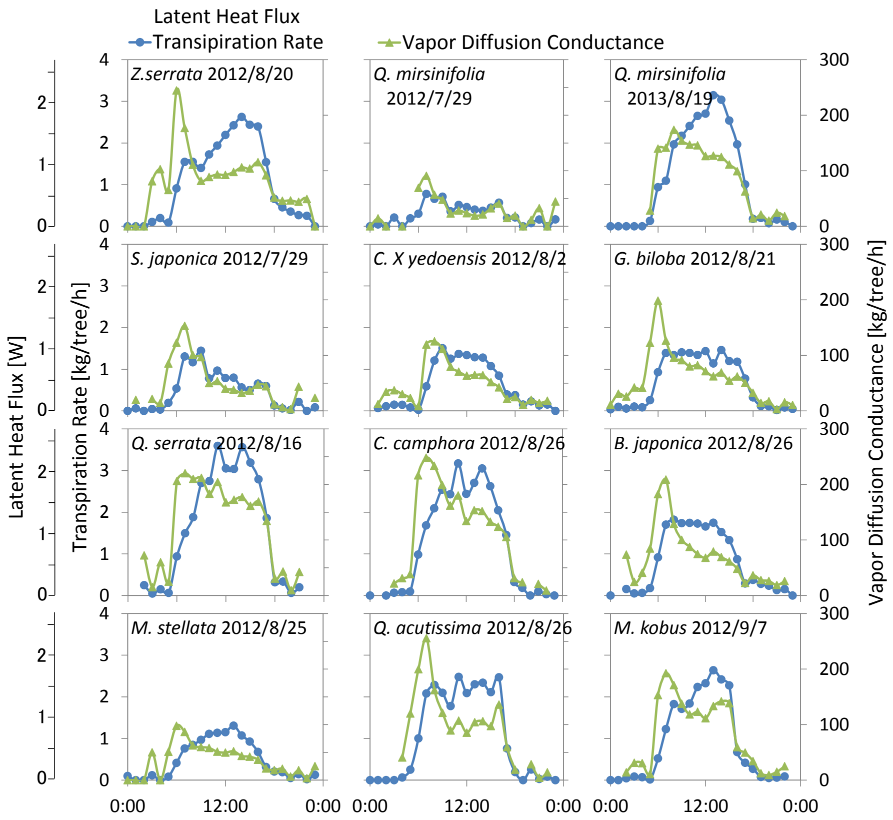

Figure 4. Measurements of whole-tree transpiration and vapor diffusion conductance, and estimations of latent heat flux

Analysis of Dayly Transpiration Amount Based on Potential Evaporation

Priestley–Taylor Equation. Transpiration is influenced by meteorological conditions, so this section analyzes and compares the transpiration characteristics among these tree species based on the standard of potential evaporation (ET_{pot}). ET_{pot} is estimated by the Priestley–Taylor equation (Eq.(3)) (Ptiestley and Taylor 1972).

$$\lambda E = 1.26 \frac{s}{s+\gamma}(R_n - G) \tag{3}$$

The Priestley–Taylor equation is a semi-empirical model that predicts the evaporation rate of water surfaces based on the heat balance. The coefficient, 1.26, on the right side on the equation was empirically obtained from measurements on water surfaces, on which there was no horizontal advection. The heat conduction, G, was assumed to be negligible in this study.

Creation of a Database of Daily Transpiration Amounts Per Ground Area. Figure 5 shows the ratio of the measured transpiration amount to potential evaporation (ET/ET_{pot}) during clear sky and water supply conditions. In the field of hydrology and meteorology, the crown projection area is generally used as a standard when comparisons are made with potential evaporation. In this study, the area of the planter (1m × 1m) is also used as a standard, as well as the crown projection area.

The average and standard deviation of ET/ET_{pot} was 0.6 ± 0.3, when using the standard of crown projection area. The reason why this averaged value was smaller than 1 is that the stomata restricted transpiration to prevent water loss. This result corresponds to previous measurements made in forests and croplands. Although ET/ET_{pot} is smaller than 1 on average, *Cinnamomum camphora* displayed a value of 1.1 in this experiment. It is considered that the transpiration amount of *Cinnamomum camphora* is large for its crown size, and that the transpiration rate per LAD and leaf area is also high.

The averaged value and standard deviation of ET/ET_{pot} was 2.7 ± 1.1 when using the standard of planter area, and this large value is due to the fact that the transpiration area of the crowns is much larger than the planter area. This result indicates that the planting of tall trees is more effective than the use of water surfaces in urban spaces, because the space under the crown can be used while obtaining the cooling effect.

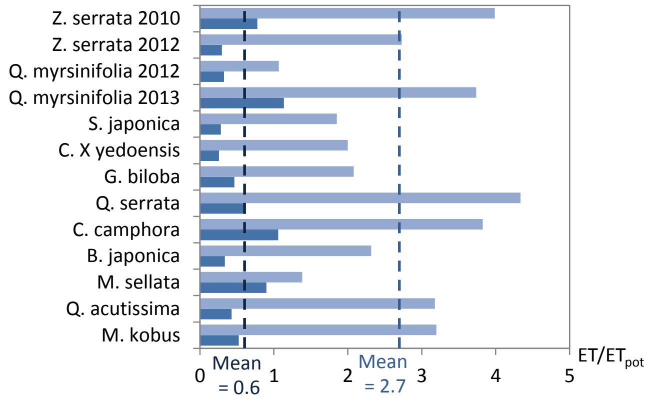

Figure 5. Daily transpiration amount per ground area (ET/ET_{pot}, Clear sky and water supply conditions)

Influence of species and crown features. Figure 6 shows (ET/ET_{pot}) for all tree species when using the standard of planter area. In general, there is a correlation between whole-tree transpiration and leaf area, so it is considered that there is also a correlation between whole-tree transpiration and the crown projection area and basal diameter. However, an obvious correlation could not be confirmed in Figure 6. In future studies, we intend to analyze the effect of LAI (Leaf Area Index) and LAD (Leaf Area Density) on whole-tree transpiration.

Focusing on differences in xylem porosity, *Quercus acutissima*, *Zelkova serrata* and *Quercus serrata*, which are ring-porous and have thick trachea, showed relatively large transpiration amounts. In general, the photosynthetic rate is inversely proportional to leaf life-span, and transpiration and photosynthesis are simultaneously controlled by the stomata. Therefore, we expected a difference in transpiration amounts based on leaf life-span (evergreen or deciduous), but any clear differences were not observed.

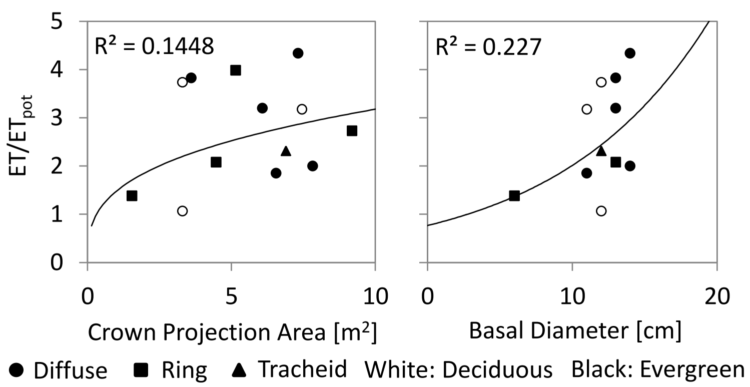

Figure 6. Relationship between daily transpiration amount and tree characteristics

Relationship between Soil Water Content and Transpiration

Transpiration characteristics depend on soil water content. In many urban spaces, planted trees often suffer from water stress, due to insufficient precipitation and water supplies (Kagotani et al. 2013). Figure 7 shows measurements collected during the water stress test, in which the water supply was stopped for three days from August 24 to 26, 2010. The soil water content shown in Figure 7 is the averaged value of five measurements taken at different depths. The transpiration rate and vapor diffusion conductance decreased as soil water content decreased. The peak value of the transpiration rate and vapor conductance decreased to one third and one half, respectively, from August 24 to 26. The pak value of latent heat flux decreased from 2 kW to 0.7 kW by the water stress of the tree. This means that the cooling effect decreased to one third. Although the water supply was resumed early on the morning of August 27, the transpiration rate on the day was almost equal to that observed on August 26. Therefore, transpiration did not recover quickly from water stress.

Figure 8 shows the transition in soil water content and vapor diffusion conductance during the water stress test. The relationship between soil water content and vapor conductance was hysteretic after the water supply was halted and resumed. A decrease in vapor conductance appeared two days after the supply of water was stopped, and it recovered three days after water supply resumption. This finding suggests that soil water content levels should be considered during any evaluation of the cooling effects of trees in urban environments.

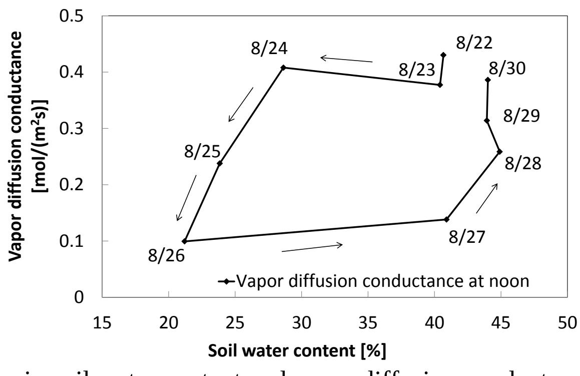

Figure 8. Transition in soil water content and vapor diffusion conductance (*Zelkova serrata*)

CONCLUSIONS

This paper shows the characteristics of whole-tree transpiration rates for urban tree species, using a weighing lysimeter. The daily transpiration amounts of the trees, whose heights ranged from 3 m to 7 m, varied from 10 kg to 30 kg under clear sky and water supply conditions during the summer. The ratio of the daily transpiration amount to potential evaporation was 0.6 $\pm$ 0.3, when using the standard of crown projection area. The vapor diffusion conductance peaks appeared in the morning, and that of transpiration appeared in the afternoon under clear sky conditions. The peak values of the transpiration rate for tree species that displayed large transpiration amounts were over 3 kg/h. This value is equivalent to more than 2 kW and 400 W/m^2 of latent heat flux. A peak in transpiration rate for these trees varied from 1.3

kg to 3.6 kg. These values are equivalent to the range from 880 W to 2400 W for latent heat flux and the difference of 1500 W is regarded as the difference in the cooling effect. The peak values of transpiration rate and vapor diffusion conductance decreased with soil water content. The cooling effect of the tree decreased to one third when the tree was under water stress. The relationship between vapor conductance and soil water content was hysteretic when soil water content was varied by the water-supply stop test. A decrease in vapor diffusion conductance appeared two days following the cessation of the water supply, and it recovered three days after water supply resumption. This observation suggests that soil water content levels should be considered for the evaluation of the cooling effect of trees in urban environments.

ABSTRACT

Double Skin Façades (DSFs) are becoming increasingly popular architecture for commercial office buildings. Although DSFs are widely accepted to have the capacity to offer significant passive benefits and enable low energy building performance, there remains a paucity of knowledge with regard to their operation. Identification of the most determinant architectural parameters of DSFs is the focus of ongoing research. This paper presents an experimental and simulation study of a DSF installed on a commercial building in Dublin, Ireland. The DSF is south facing and acts to buffer the building from winter heat losses, but risks enhancing over-heating on sunny days. The façade is extensively monitored during winter months. Computational Fluid Dynamic (CFD) models are used to simulate the convective operation of the DSF. This research concludes DSFs as suited for passive, low energy architecture in temperature climates such as Ireland but identifies issues requiring attention in DSF design.

INTRODUCTION

A Double Skin Façade (DSF) or Multi Skin Façade (MSF) is generally composed of a glazed curtain offset from the line of the building envelope (Figure 1). DSFs have continued to increase in popularity, particularly in commercial architecture, yet still today there remains a paucity of comprehensive studies proving the benefit of DSFs in different climate regions, and at different seasons. Although there are many published case studies *e.g.*(Hashemi, Fayaz, & Sarshar, 2010) (Pasquay, 2004) a lack of reliable experimental data and validated simulation studies is oft commented in the literature (Gertis, K., 1999) (H. Manz, Schaelin, & Simmler, 2004).

Ever more studies of DSF systems are required as their characteristics and operation are directly related to the climate in which the building is located, with solar radiation, wind and ambient air temperature all having an impact. This paper presents an experimental study focused on the temperature profile in a DSF in the maritime Irish climate during winter. This experimental study will form the basis for an extensive Computational Fluid Dynamics (CFD) study of different configurations of MSFs in the maritime climate. This study will in turn enable an evaluation of the appropriateness of MSFs in the context of the Irish climate and their ability for energy savings and comfort enhancement in Irish buildings.

DSFs are generally designed for different operation in summer and winter conditions. During Irish summer months DSFs generally operate in the 'open' mode. This implies that vents are opened at the bottom and top of the façade cavity. The air in the cavity removes excess heat by means of convective

Oliver Kinnane is an Assistant Professor of Façade Engineering in the Department of Civil, Structural and Environmental Engineering, Trinity College Dublin, Ireland. Tom Prendergast is a graduate of TCD and a Project Engineer at KEO International Consultants.

flow induced by the stack effect. This action prevents excessive heat accumulation in the cavity. If this occurs unwanted heat can transmit into the internal spaces. This can have a significant impact on the thermal comfort conditions within the building and create a greater necessity for the use of auxiliary cooling systems, hence resulting in an increase in energy consumption.

When the air is cleared from within the cavity, the temperature of the building envelope skin is lowered and heat transfer from the internal skin to the occupied space is reduced. Accordingly less heat is transferred from the outside to the inside, and less energy is required to cool the space.

In winter common DSF operation utilizes a sealed cavity, with no air circulation. For the winter scenario, the DSF cavity is warmer than the exterior temperature. As the air in the cavity is heated by the sun the temperature of the envelope skin increases and the temperature difference across the envelope skin reduces. Accordingly less heat is transferred from inside the building to the outside given a reduced temperature differential between interior conditioned space and the adjacent thermal zone. Significantly less energy is required to heat the space.

A greater proportion of research focuses on the evaluation and modeling of the summer operation of DSFs (H. Manz & Frank, 2005) with a paucity of investigation of the winter thermal buffer effect. Similarly the majority of studies investigate the airflow in DSFs with less emphasis on investigation of the temperature profiles in the cavity. In an 11 story building in Iranian winter conditions Hashemi et al (Hashemi et al., 2010) document a difference in temperature of 5–12 ◦C on the 7th floor and on 11th floor 7.5–10.5 ◦C more than the outside temperature. Vertical thermal stratification in the cavity is common in DSFs. The heated air in the cavity rises due to natural buoyancy, and a drop in air velocities at the top of the cavity leads to stratification. Thermal stratification is identified in monitored data (Hashemi et al., 2010) and simulation studies of mechanically ventilated facades (Pfuhler, Sikorski, & Kuhn, 2012). Hamza and Abohela (Hamza & Abohela, 2013) present an exploratory study of cavity stratification in non-uniform DSFs. Thermal stratification in the cavity has been shown to be influenced by a number of design and climatic parameters including solar radiation levels, shading device use and their colour, depth of the cavity of the double-skin, glazing types on both façade layers and design of inlets and outlets in relation to prevailing wind direction and speed amongst others.

This paper presents an experimental monitoring study of the temperature profile in the DSF of a commercial building in Dublin, Ireland that will form the basis of an extensive and validated modeling study of the appropriateness of DSF for this and similar climates. The impact of solar radiation levels, surface and cavity temperatures on DSF operation are presented.

EXPERIMENTAL METHODOLOGY

Experimental monitoring of a case study DSF is presented with focus on temperature characterization. Temperatures in the DSF were extensively monitored, with 9 temperature sensors installed on the three floors of the cavity. Interior temperature and external temperature are also monitored. Surface temperature readings were taken at intervals. Solar irradiance data was also attained for the location.

The DSF under consideration in this study is installed on the upper stories of an office building in Dublin, Ireland. It is a three-story façade (width x depth = 12m x 0.7m), is south facing and composed of external double-glazing and a single interior sheet of glass. The air cavity includes timber sun-shading louvers that drop approx. 750mm from the top of each level, are 250mm wide and horizontal. Automated venetian blinds shade the building envelope skin, and adjust their angle throughout the day. A metal grill divides each level of the DSF, which enable accessibility to each level and air movement between levels.

Although the DSF is analyzed in the ‘closed’ state there are 10mm gaps between the 100mm louvers, which allow ingress and exhaust of air. Such small openings have been shown to generate significant air flows (Gratia & De Herde, 2004).

a) b) c)

Figure 1 a) Double skin façade on upper stories of commercial building, b) corridor of double skin façade, and c) vents in closed state, with air gaps evident between louvers.

Dublin is located on the eastern coast of Ireland, on the northwestern periphery of Europe (latitude: 53°20′N and longitude: 6°15′W). It has a temperate maritime climate, of mild winter and summer seasons.

RESULTS

Winter temperatures were measured from January to April 2014. The following figures document the typical observed temperature profile for the DSF.

Cavity temperatures. The temperature in the 3 Levels of the cavity over a typical 4-day period in February is shown i**n** Figure 2**.**

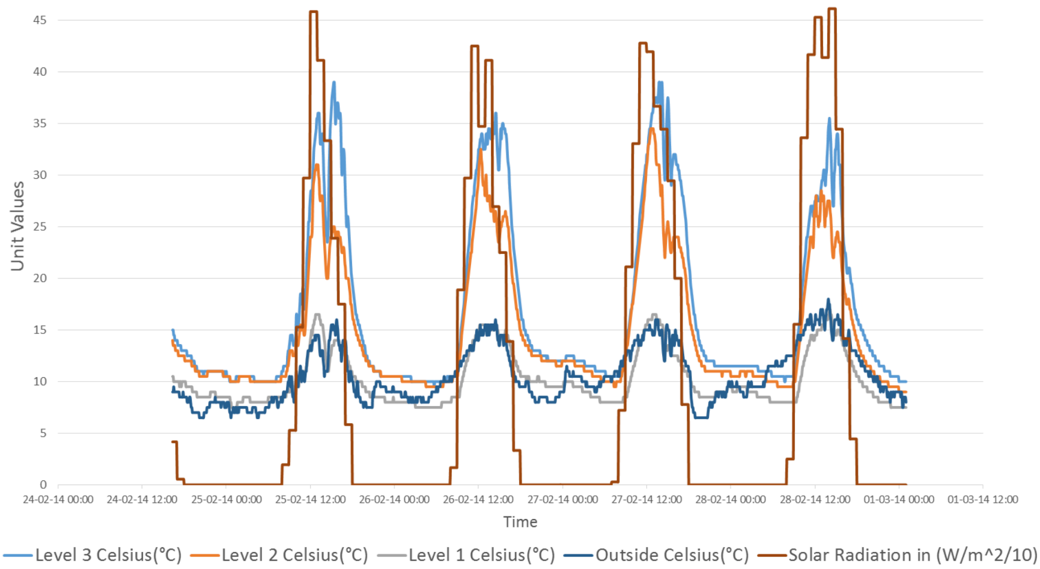

Figure 2. Temperature profile over 4 days of a typical sunny winter week, with outdoor temperatures in an 8-15°C circadian swing. Solar radiation is shown in brown and scaled to $(W/m^2)/10$.

The results show that T_{cav} during the day and night exceeds T_o on all levels except Level 1 of the cavity. The air temperature on Level 1 deviates little from the outdoor temperature but is often below even when exposed to high solar radiation. This phenomena is further shown in Figure 3 and 4. The outside temperature fluctuates in a 6°C range, whereas the temperature fluctuations in Level 2 and 3 are in the range 20-28°C on different days. This is in contrast to other studys in winter conduitions that show the fluctuation in T_{cav} to be less than that of the outside temperature (Hashemi et al., 2010). The temperature difference between the cavity temperature on Level 2 (T_{cav2}) and outside is 18°C at midday and 2-3°C at night. Similarly for Level 3, T_{cav2} - T_o is approx. 20°C at maximum and 2-3°C at nighttime. Maximum T_{cav3} reaches 35-39°C, when the outdoor temperature is 15°C. These high cavity temperature on the upper levels reduce the temperature difference across the building envelope, thereby impacting the heat loss across this boundary.

Temperature and solar incidence. Figure 3 and Figure 4 show the solar irradiance and the temperature on each level of the DSF for typical sunny and overcast days, charaterised by high and low solar radiation. T_o differs by 5°C between the days shown. However, T_{cav3} is almost 18°C higher on the sunnier and warmer day, showing the significant impact of solar radiation on a closed cavity in winter in sunny conditions.

Vertical thermal stratification is evident between the different façade levels with a large jump from the inlet level (T_{cav1}) to the middle of the façade (T_{cav2}) of up to 12-15°C.

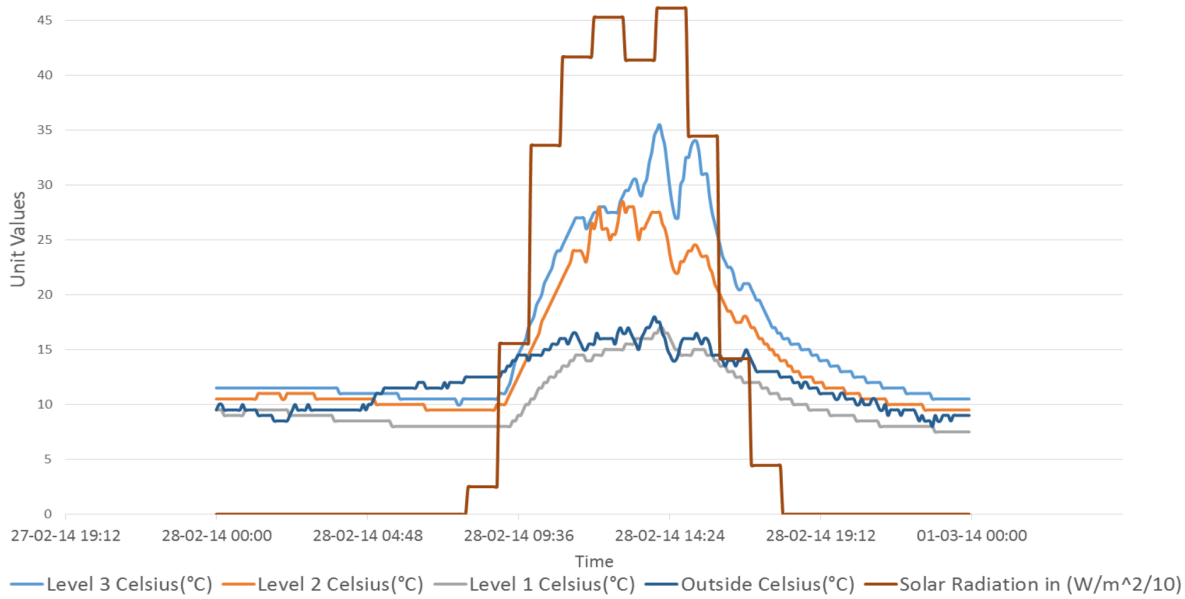

Figure 3. Temperature profiles for each level of the façade on a typical sunny day. Solar radiation (brown) is scaled to (W/m^2)/10.

In contrast on a typical overcast day the temperature in T_{cav1} is 2-4 greater than T_o. It is difficult to explain this given that all Levels of the cavity are exposed ot high solar radiation with no over-shadowing. The surface temperatures of the walkway grill and glass at Level 1 are signicant lower than temperatures at other levels and these possibly act to reduce the air temperatures in

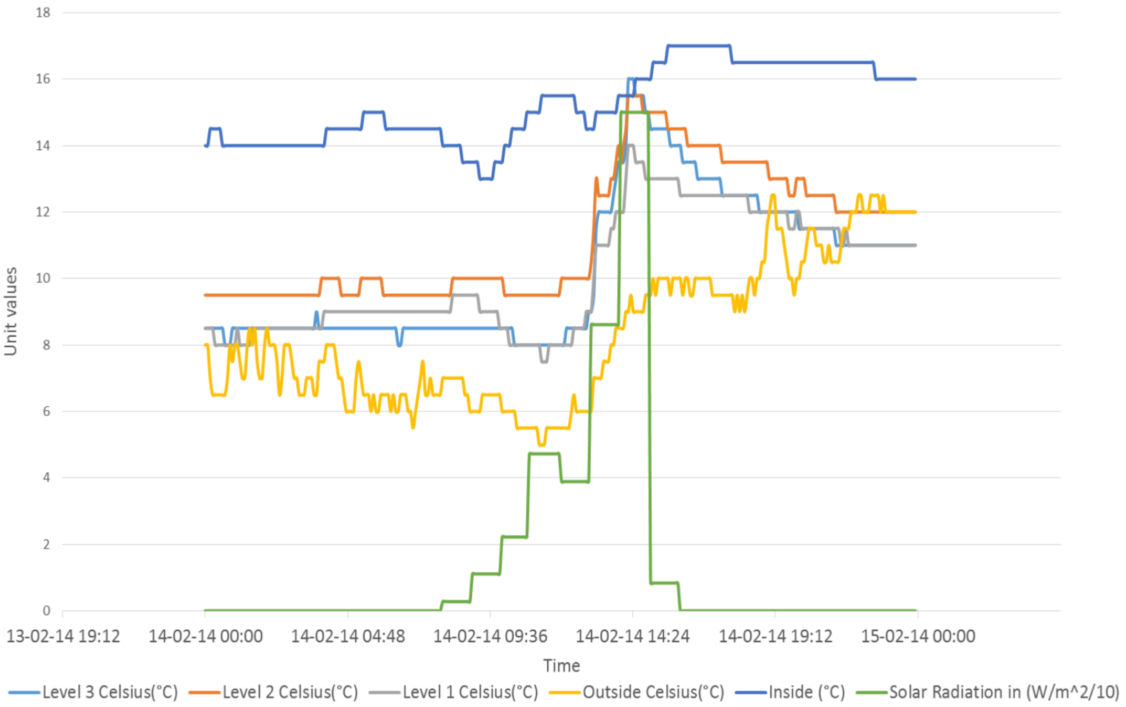

Figure 4. Temperature profiles for each level of the façade cavity on a typical overcast day. Solar radiation (green) is scaled to (W/m^2)/10.

Surface and cavity temperatures. Outdoor, indoor and cavity air, and boundary layer surface temperatures are **shown in** Figure 5**.** On this day the temperature in the interior space is controlled by the BMS from rising above 24°C. The surface temperature of the internal face of the building envelope boundary gains heat from the auxiliary internal space heating. Although Figure 5 shows temperatures for a discrete day of average solar radiation, the temperature profiles display a common trend on the different levels. The temperature gradient across the building envelope glazing surface drops in the upper floors; $T_{env\_ext\_3s}$ - $T_{env\_int\_3s}$ = 3.5°C and $T_{env\_ext\_3s}$ - $T_{env\_int\_3s}$ = 1.5°C. The gradient in surface temperature in Level 1 in contrast, increases $T_{env\_ext\_1s}$ - $T_{env\_int\_1s}$ = +5.8°C.

As expected, and similar to results reported by studies in hot arid climates Hamza et al (Hamza, Gomaa and Underwood, 2007), the surface temperature on the in-cavity surface of the exterior glazing of the DSF (T_{dsf}) is lower than the surface temperature of the in-cavity surface of the building envelope glazing (T_{env_ext}).

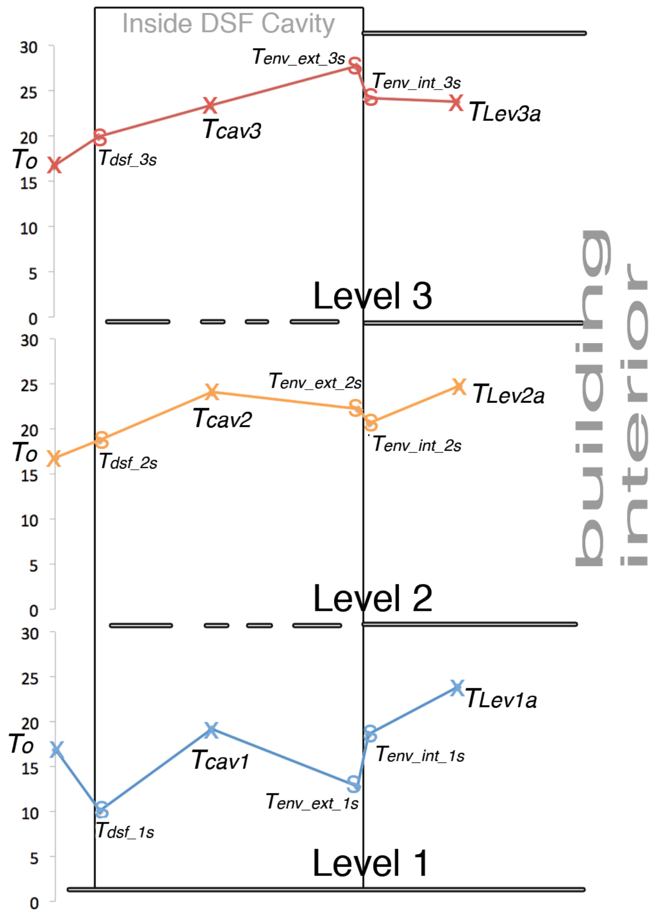

Figure 5. Temperatures outside, inside and on glass surfaces of DSF on a given day of average solar radiation (18/03/14). The points close to the DSF boundary and building envelope marked (s) represent surface temperature readings.

In Figure 5, Levels 2 and 3 cavity temperatures (T_{cav2}, T_{cav3}) are approximately equal to the indoor air temperatures (T_{Lev2a}, T_{Lev3a}). On Level 1 the cavity air temperature is significantly lower than on Level 2 and 3 (approx. 5°C lower) and on Level 1 the air temperature in the cavity is lower than that in the conditioned space in the building interior

SIMULATION STUDIES

Data presented in this paper is being used as the basis for a comprehensive simulation study of (i) zonal energy analysis using EnergyPlus and (ii) CFD modeling study using ANSYS. Further monitoring is planned during coming summer and winter seasons to enable validation of CFD and energy models. This will enable assessment of the specific conditions a DSF can benefit building performance and the optimum configuration and operation of the façade to enable passive heating and cooling and hence energy savings for the building. Airflow patterns in the closed and open states are investigated for turbulent and laminar patterns given different boundary conditions.

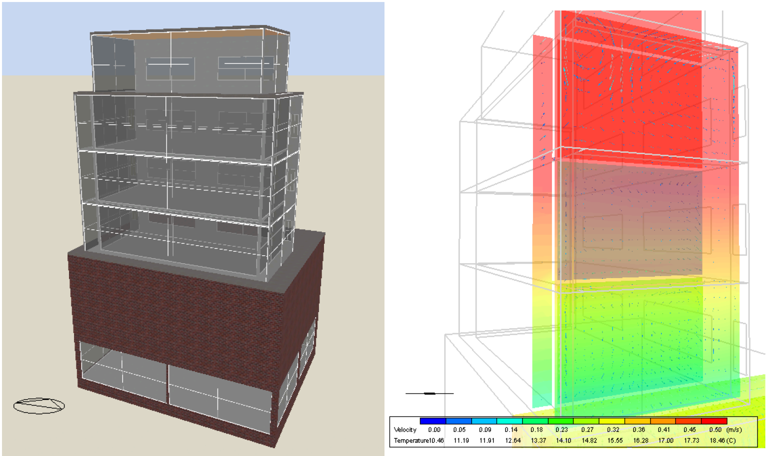

Figure 6. Energy model and CFD simulation of same model developed using EnergyPlus

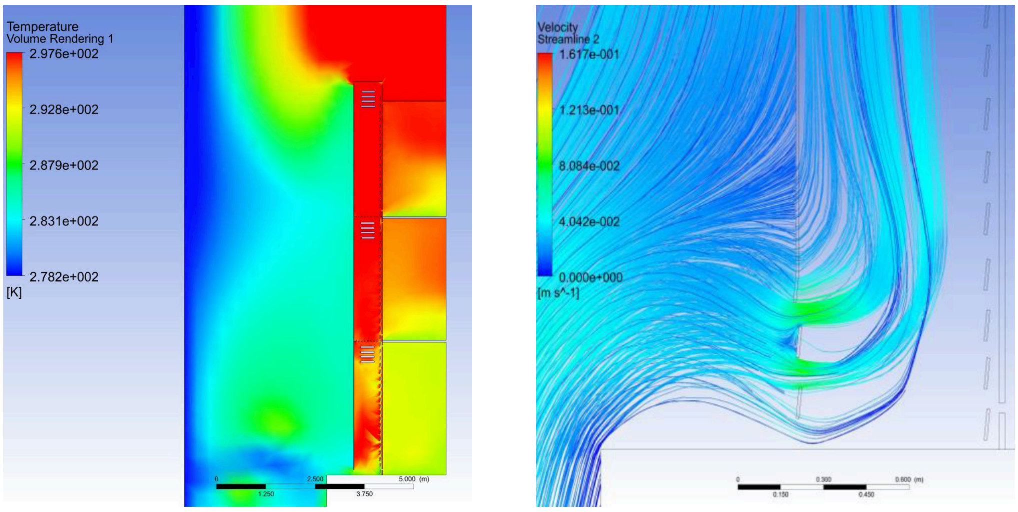

Figure 7. CFD model developed to assess temperature and laminar flow patterns in the DSF

CONCLUSION

Due to these higher air temperatures in the cavity relative to the outdoor temperature the external walls lose heat more slowly. This is beneficial to preheating of the inside spaces and heating energy conservation. However, in the DSF close to the building envelope the air temperature is often significantly higher than the heating set point implying a reversal of the standard winter temperature gradient seen across single skin building envelopes. Hence, the DSF can act to increase the internal air temperature even causing overheating, when the building is in free running mode. On days of high solar radiation levels it is proposed that the cavity be ventilated. Again this is not the case in Level 1, where the cavity temperature is regularly up to 10°C lower. Hence, the thermal buffer benefit of the DSF at the lower level is not discernible.

In contrast to many studies in the literature this study documents a consistently lower inlet temperature than outdoor air temperature. Saelens et al (Saelens, Roels, & Hens, 2004) demonstrated that the difference between the inlet temperature and the outdoor air temperature depends on the solar intensity and airflow rate. With solar radiation they showed the inlet temperature to be higher than the outdoor temperature, as did other authors (Heinrich Manz, 2004) (Fuliotto, 2010). Based on a review of these studies He et al (He, Shu, & Zhang, 2011) use a constant difference of +4°C difference in the summer case and +2°C difference in the winter case, between the inlet temperature and outdoor air temperature.

Based on standard heat loss assessment through the building envelope the DSF can be beneficial to

Low-Energy Industrial Buildings for Climates of Emerging Countries

Pascal Brinks

René Oly
Lindab S.A., Luxembourg

ABSTRACT

The economic growth of developing and emerging countries pushes particularly the industrial sector, why a large demand for new industrial buildings arises. Though in many of these markets there is no traditional climate adapted architecture for industrial buildings as it mostly exists for dwellings. Thus many buildings for industrial applications are mainly built after European or American standards without respecting the local climate. Missing or misleading building regulations as well as missing general awareness and know-how in the local communities enhance this problem. The risk is to build a new generation of industrial buildings in these countries, having an unnecessary high energy demand for heating and cooling just by neglecting the climatic characteristics. Therefore this study proves the applicability of European concepts for low-energy industrial buildings for different climates for example from Russia and North Africa. Parameters such as air-tightness, window quality, solar orientation, thermal insulation and radiation reflectivity are analyzed and adjusted for optimizing the energy demand. The reduction of summer overheating is further under consideration because the post-installation of air conditioning systems should be avoided at any rate. For this purpose transient building simulations and air-flow-network simulations are used. As the basis for simulations of air-infiltration by appropriate product specific models, typical industrial building components are measured in an air-tightness test stand. The project focuses on light steel structure buildings which are often exported from Europe and the U.S. to emerging and developing markets. It is demonstrated how the energy demand of such buildings can be decreased already by small but efficient design changes.

INTRODUCTION

Emerging Countries mainly gain their economic growth by the industrial sector for which low labor cost and natural resources are usually the push factors. Thus a particular demand for new industrial buildings arises in these countries. However as large scale industry has often no tradition in these newly industrializing countries there is even little experience in buildings for industrial applications. For dwellings there is usually a long building tradition that was adapted for the local climate. But production buildings or plants are often imported from western regions such as Europe or the US. Due to the shipping constraints such imported buildings are usually built in light steel structure. Their design is typically executed in the producing country why the local climate and environment is often not well considered. Furthermore many of the companies settling down in threshold countries are global players who have already standardized their production buildings based on western climate requirements. Often only the insulation thickness is simply increased or decreased whether the building will be erected in a

P. Brinks is a PhD student at the Technical University Kaiserslautern, Germany and in the R & D of Lindab S.A., Diekirch, Luxembourg. O. Kornadt is a professor and head of the department Building Physics / Low-Energy Buildings at TU Kaiserslautern, Germany. R.Oly is R & D Director at Lindab S.A., Diekirch, Luxembourg.

"warm" or "cold" climate. Other parameters such as window orientation or air-tightness are rarely recognized. Moreover the local authorities do not always have the expertise to assist and building regulations setting an energy standard as in Europe mostly do not exist or are at least less elaborated, as e.g. in Russia where the last recast of the building regulations dates from 2003 (SNiP 23-02-2003, 2003). That goes along with a still missing awareness for the need for reducing GHG-emissions. The risk is to build a new generation of industrial buildings having an unnecessary high energy demand. Hence in this project the energy demand for heating and cooling of light steel industrial buildings was analyzed for different climates. These analyses were determined by transient building simulations using the software package TRNSYS.

CLIMATE

As every climate needs an individual design, only general advises can be given in this project to make designers aware for how to reduce the energy demand dependent on the climate. For this purpose two hot North African climates (Casablanca, Morocco and Dar El Beïda, Algeria) and three cold Russian climates (Moscow, Samara and Irkutsk) were selected. Besides Ankara (Turkey) was chosen as this climate is hot in summer and cold in winter. A typical climate for exporting Central European countries is Würzburg, Germany. Exemplary the data for Irkutsk, Dar El Beïda and Ankara is shown in figure 1-3. Most important is the outside temperature, but also the solar radiation, the wind velocity and the temperature difference between day and night have a certain impact on the building performance.

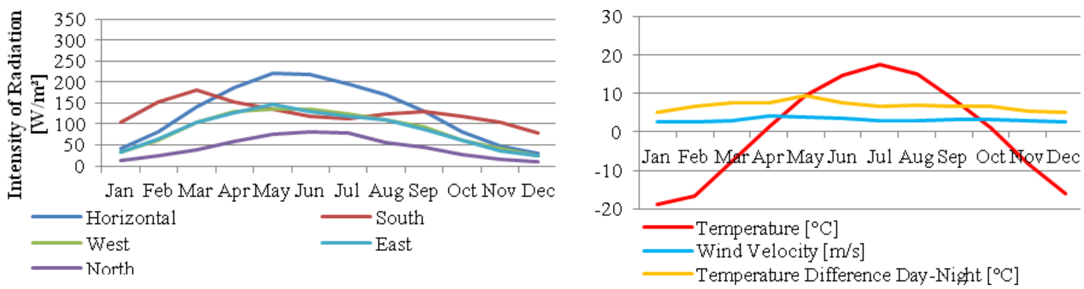

Figure 1 Radiation, temperature and wind velocity (Meteonorm) for Irkutsk (South Siberia)

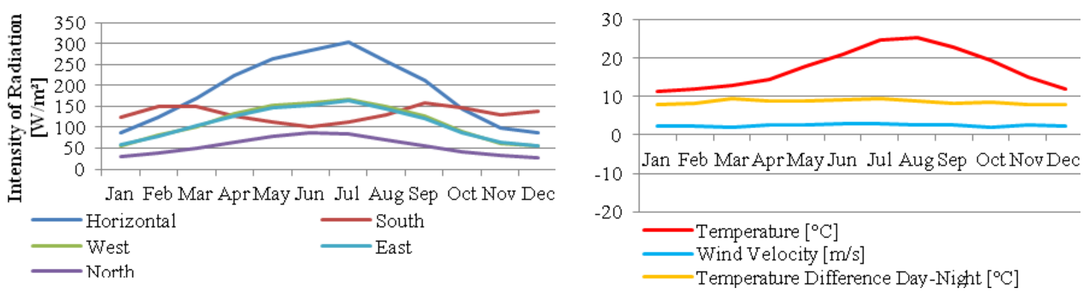

Figure 2 Radiation, temperature and wind velocity (Meteonorm) for Dar El Beïda (Algeria)

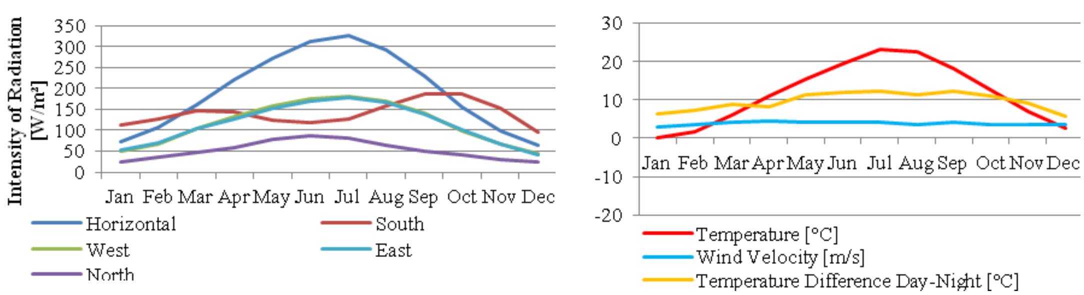

Figure 3 Radiation, temperature and wind velocity (Meteonorm) for Ankara (Turkey)

BUILDING PERFORMANCE

Industrial buildings in warm climates as Dar El Beïda or Casablanca usually never have any heating device. The temperatures during daytime are usually high enough also in winter and the temperature requirements in such buildings are in general quite low. Also cooling devices are still rare due to high investment and energy costs even if a cooling demand actually exists. But the economic growth will allow the installation of more and more air-conditioning systems in the future. To reduce the costs and the emitted GHGs, and of cause to improve the thermal comfort, the focus must therefore be set on overheating protection. Post-installation of cooling devices caused by misleading building design should be avoided at any rate. For the cold Russian climates cooling is not required, even if some hot summer days exist in the continental Siberia, but these temperature peaks are usually buffered by the thermal mass of the interior and the concrete slab. Most difficult is the design for climates like in Ankara, where the average temperature in July and August reaches 23 °C and in January it goes down to 0 °C. To find the right balance between a passive solar building and reduced summer overheating is the challenge.

Summer Overheating

The main summer overheating problems arise by wrong orientation of glazed surfaces. Movable shading devices are often not applicable and usually too expensive for industrial buildings. As summer overheating is a minor problem in Central Europe and as illumination is easy to ensure with horizontally oriented glazed surfaces, many exported industrial buildings have skylights. Figure 4 shows the simulated influence of the orientation and size of glazed surfaces in a typical light steel industrial building (1950 m^2 ground area, concrete slab). Internal loads by machines were considered with 40 W/m^2, as also used for production buildings in (DIN V 18599, 2011), based on (VDI 3802, 2003). In figure 4 the overtemperature degrees over 27 °C are shown. This method is used in Germany to limit overheating (DIN 4108-2, 2013). It sets a limit of 500 Kh per year which must not be exceeded if no air condition exists. Figure 4 shows that this limit is usually not reached in Central European climate why skylights are less critical. In warm climates like Ankara or Casablanca the horizontal orientation of glazed surfaces causes vast overheating if no air-condition exists and no controlled ventilation is used. If vertical glazed surfaces are used and oriented to the north the overheating is reduced significantly compared to skylights. The vertical south orientation also improves the overheating but for buildings without any heating demand the north should always be preferred. West and east oriented glazing is usually critical as well why for deeper buildings a combination of north and south oriented glazed surfaces in the facades is reasonable for North African Climate. For maritime climates like Casablanca the climate can already get tolerable by avoiding skylights. But for continental climates like Ankara other actions are required.

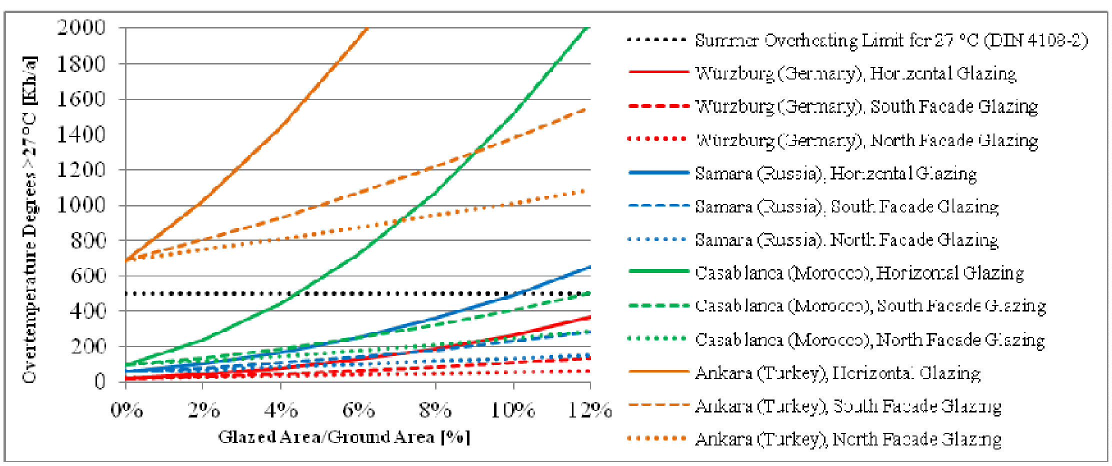

Figure 4 Overtemperature degrees (Kh/a > 27 °C) for different climates and glazing orientations

Figure 5 shows the impact of a controlled ventilation which is always turned on when the inside temperature exceeds the outside Temperature. Costs and energy demand of such ventilations are much lower than of air-conditions. Such mechanical ventilation should also be supported by natural ventilation to save energy, which can reach high ventilation rates like shown for the ventilation of industrial buildings in (Kistelegdi and Háber, 2012). Already existing openings like industrial doors and smoke vents can be used for it. How openings can be optimized for summer ventilation is e.g. analyzed in (Stephan, Bastide and Wurtz, 2011). Cross-ventilation though large openings like industrial doors including wind influences is discussed in (Seifert et al., 2006).

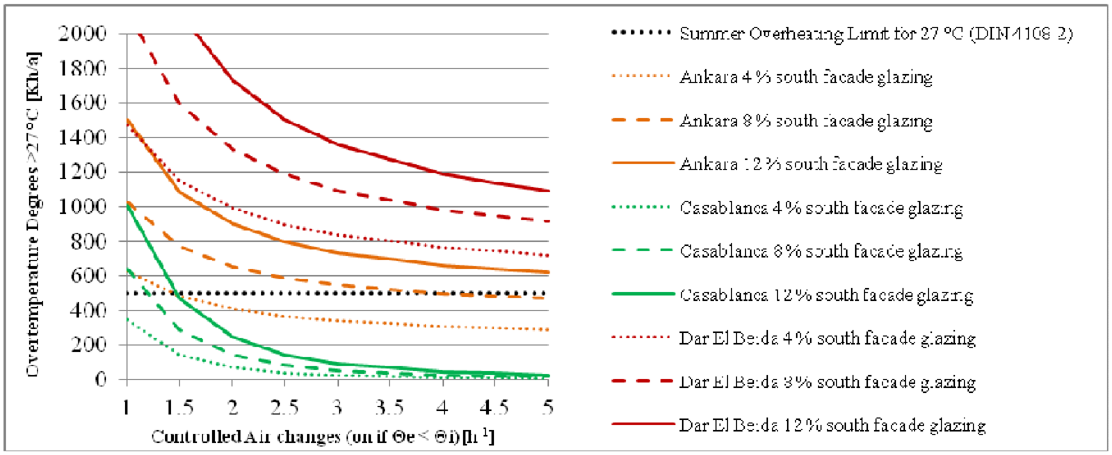

Figure 5 Influence of controlled ventilation on the summer overheating

The simulations in figure 5 show that even the German overheating requirements can be met for Ankara with glazed surfaces in the south façade, if there is a strong controlled ventilation. This is mostly due to the high temperature difference between day and night visible in figure 3. For Casablanca with its coast to the Atlantic Ocean the summer overheating is quite easily to reduce by controlled ventilation. At the Algerian coast to the Mediterranean Sea (Dar El Beïda) overheating is again much more difficult to avoid. Here the north orientation should always be chosen for window orientation.

In addition to the window orientation and the ventilation also the solar absorptance of the building envelope and the thermal capacitance of the interior are deciding for the thermal comfort in summer. Figure 6 (a) shows that an overheating reduction by low absorbing coatings is possible but the effect is not as important as e.g. night ventilation.

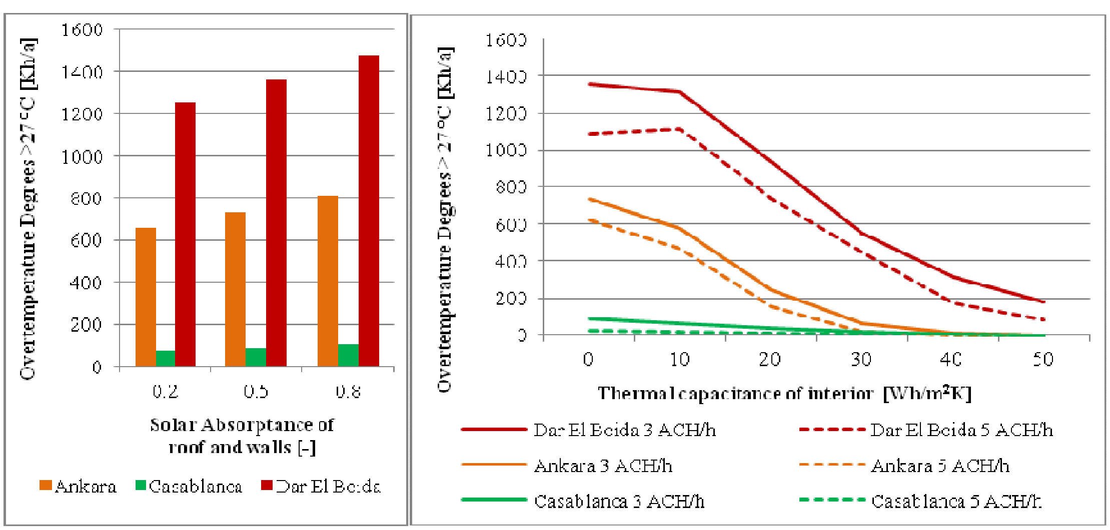

Figure 6 (a) Influence of the solar absorptance of the building envelope (roof, walls)
(b) Influence of the capacitance of interior on summer overheating (glazing south)

Figure 6 (b) shows the other important parameter, the thermal capacity of the interior. This of course interacts with the ventilation, as a higher capacitance can only reduce the inside temperature if the thermal mass is regularly cooled down by ventilation. The considerable effect is visible but anyway the simulation results can just be seen as an indicator for the importance of thermal mass. The real influence depends on many parameters such as the surface of the interior, the material and its heat-transmission resistance. These parameters will never be assessable in a design process but it is clear that an empty building overheats much easier than a filled storage.

The impact of air-tightness on summer overheating and the cooling demand is very low. In the simulations the differences between the cooling demand of an untight building (n_{50} = 5 h^{-1}) and a very tight building (n_{50} = 0.5 h^{-1}) was only about 2 %. Anyway big leakages should always be avoided.

Heating Demand

Air-tightness. Aside from the thermal insulation of a building the air-tightness is a major parameter for the energy performance. In many European countries like Germany, UK and France, tightness requirements already exist also for industrial buildings D: (EnEV, 2014), UK: (The Building Regulations 2010, 2013), F: (Méthode de calcul Th-BCE 2012, 2012). Even if these requirements are not always mandatory to meet, verifying the tightness allows lowering the infiltration losses in the energy performance calculation. In Russia unfortunately only tightness requirements for single building components of industrial buildings exist (SNiP 23-02-2003, 2003). To check if these single requirements are met is not possible on site and also fan pressurization tests after erecting the building are usually not carried out. This leads to a lower workmanship on site and probably increases the infiltration. In particular for cold Russian climate this is very critical. As air infiltration is caused by wind pressure and stack effects, beneath the wind velocity also the difference between the internal temperature and the ambient temperature is deciding for the amount of infiltration losses (Brinks, Kornadt, and Oly, 2014a), (Younes et al., 2011). Thus the infiltration in cold climates like Russia is even much higher than in temperate European zones. In warm climates like North Africa, where buildings are not heated and the climate inside and outside is similar during the year, infiltration is rather small (see figure 7). Adapted from measurements in an air-tightness test stand and air-flow network simulations, an infiltration model described in detail in (Brinks, Kornadt, & Oly, 2014b) was developed. This model was used to simulate the infiltration for typical light steel industrial buildings in the here mentioned climates. Detailed information about the air-flow network model is given in (University of Wisconsin Madison, 2009) and (Weber et al., 2003). In figure 7 the results for the infiltration of an 8 m high building (65 m x 30 m) with an n_{50}-value of 3 h^{-1} are shown. Due to the low temperatures in Irkutsk the infiltration is much higher during winter than for warm climates like Dar El Beïda.

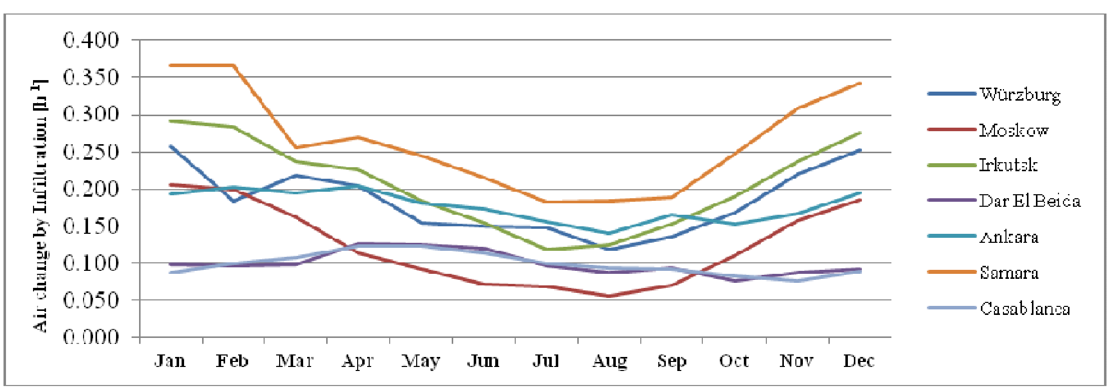

Figure 7 Air infiltration for an industrial building (n_{50} = 3 h^{-1}) in different climates

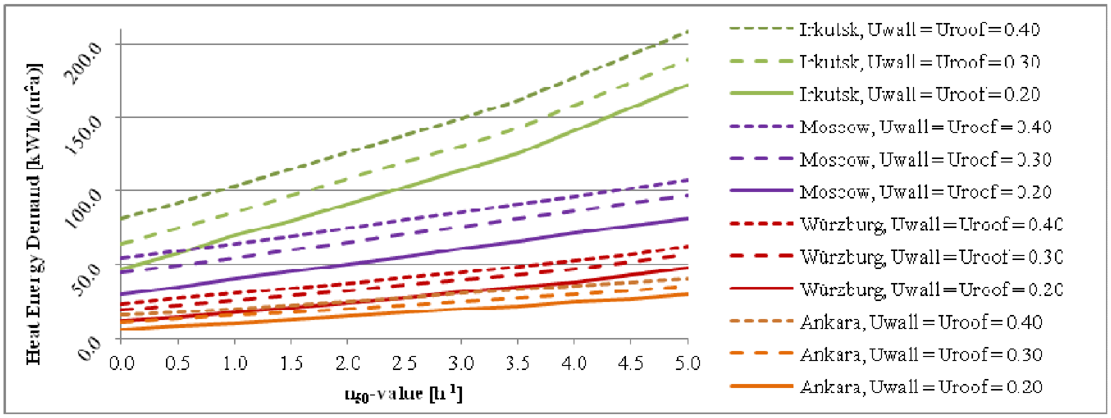

Figure 8 Heat energy demand dependent on the tightness and the wall and roof insulation quality

Figure 8 shows the impact of the tightness on the heat energy demand. Especially for Siberia it is even more important to tighten the building than to increase the insulation thickness of the roof and walls. Reducing the n_{50}-value from 3.0 h^{-1} to 1.5 h^{-1} saves as much energy as reducing the U-value of the roof and all walls from 0.4 W/m^2K to 0.2 W/m^2K. In general promising methods for air-tightness design in light steel buildings were already developed e.g. described in (Brinks, Kornadt, and Oly, 2013). But tightness is not only a question of design but of workmanship, thus it cannot be assured, that European standards are realized in Russia as well. Anyway tightness requirements for Russian industrial buildings are currently not existing even if requirements for Russian dwellings are in the range of European standards (SNiP 23-02-2003).

Another important aspect is that infiltration losses via open doors are not recognized at all in any known building regulations or codes. For dwellings such losses may mostly be negligible but losses via large industrial doors can have a large impact on the energy balance. This lack was already discussed in (Brinks, Kornadt, & Oly, 2014c) where rough simulations based on (Dascalaki, E. et al.. 1995) were carried out. These calculations already show a significant impact for Central Europe but it seems to be even higher for Russia due to larger buoyancy effects.

Solar Gains and Orientation of Glazed Surfaces. The orientation of glazed surfaces is not only important for summer overheating, but passive solar gains can reduce the energy demand of buildings considerably. For residential and office buildings this is already shown by many studies as (Cappaletti et al., 2014) or (Boubekri and Boyer, 1993) and also first analysis for industrial buildings in Central European climates exist (Brinks, Kornadt, & Oly, 2014d). Figure 9 shows how the heating demand changes for different oriented glazed surfaces (40 mm polycarbonate, U = 1.10 W/m^2, g = 0.56) in Russian climates. Here a low-energy production building with 17 °C inside temperature, 40 W/m^2 internal gains, an n_{50}-value of 0.5 h^{-1} and a U-value of walls and roofs of 0.20 W/m^2K was simulated. Due to the high solar radiation in Irkutsk during winter (approximately twice as high as in Central Europe), here the orientation has the most significant impact.

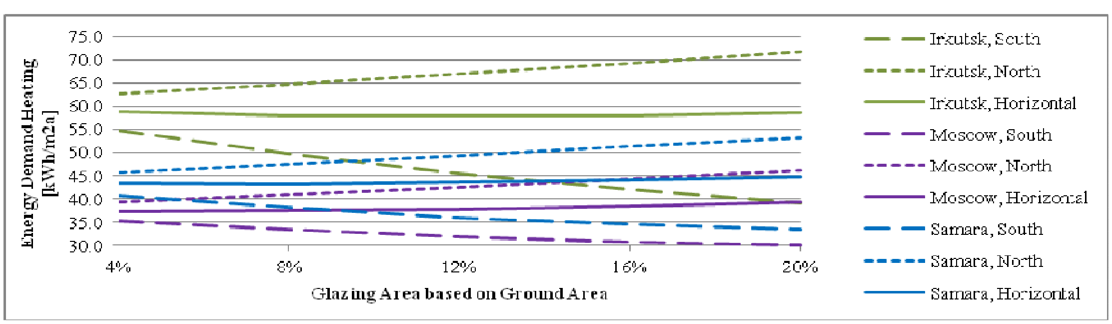

Figure 9 Energy demand for heating dependent on the glazed surfaces for Russian climates

Installing large glazed surfaces on the south façade instead of skylights can reduce the energy demand by up to 30 % if the façade is not shaded. For Moscow the effect is smaller as the solar radiation is lower. Anyway in Russian climates it is advised to use as much glazed surfaces in south façades as possible if facades are not shaded. The glazing quality, particularly a high g-value, is of course to be respected. In climates like Ankara with hot summers and cold winters the situation is more complex. Thus the impact of the glazing orientation and surface on the energy demand for both, heating and cooling, was simulated. The results in figure 10 show that increasing the glazed surface in general decreases the heating demand and increases the cooling demand. But the leverage effect of this parameter is different for all orientations. For the south façade the total energy demand (heating + cooling) decreases with a larger glazed surface. For the north façade it increases slightly and for the horizontal (skylights) it increases considerably. This means that increasing the horizontal glazing area should usually be avoided. Anyway general advises to increase the glazed south façade area in such climates cannot be given. This decision depends on if a cooling device is installed at all and which (primary) energy is used for heating and cooling. Thus a decision has to be taken individually for any project.

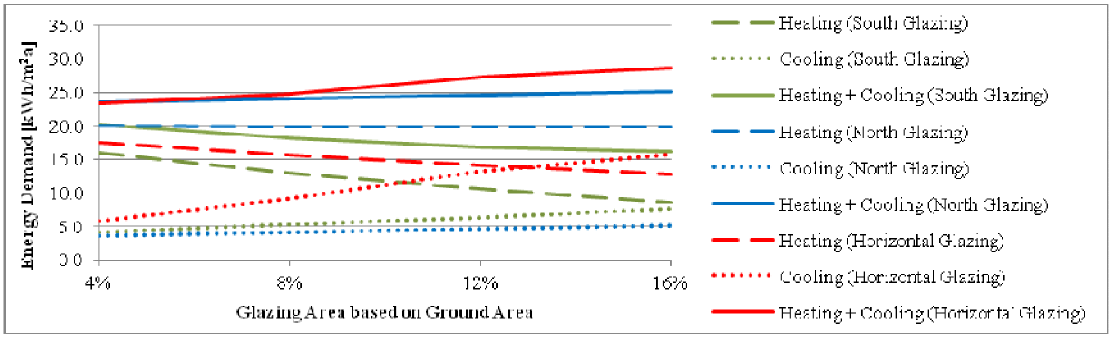

Figure 10 Energy demand for heating and cooling dependent on the glazed surfaces for Ankara

CONCLUSION

The building simulations carried out show the consequences of exporting industrial buildings designed for Europe without adapting the building envelope design to the local climate.

In hot climates it is mandatory to avoid skylights and replace them by glazed surfaces in the façade. If summer overheating is not critical and a heating demand exists in winter, the glazed surfaces should be oriented mainly to the south, otherwise to the north. To keep the cooling demand low or even avoid it, controlled night cooling is an energy-saving solution. Especially at night high ventilation rates are required that should be ensured by mechanical ventilation supported by natural ventilation. Reflective coatings of the roofs can be a small added value as well. Buildings with little thermal capacity are usually more susceptible for overheating why overheating protection becomes more complex.

In cold climates like in Russia the saving potential by orienting vertical glazed surfaces to the south is very high. Due to very high solar radiation in winter especially in Siberia these glazed surfaces should be increased as much as possible as overheating usually is no problem in such regions. Furthermore the air-tightness of industrial buildings in Russia is very important but is unfortunately not considered sufficiently by current building regulations. Improving the tightness is even more effective here than increasing the insulation thicknesses. Moreover this solution is also low cost, but appropriate quality controls like fan pressurization tests should become mandatory also for production buildings and warehouses. Here the most important need for action exists.

Most difficult is the design for regions with hot summers and cold winters like Turkey. Here building simulation should be used, as general advises are difficult to give and the design also depends a lot on the kind of energy used. A potential for heating in these countries is surely the use of solar energy. Here further research for seasonal thermal solar storages is required. Due to the long heating period and the high solar radiation in South Siberia this could also be interesting as a heating support for Russia.

ACKNOWLEDGMENTS

Flexible and Environment Responsive Mass Housing in Bangalore, India

Archana Narendran, MArch
[Glasgow School of Art]

Filbert Musau, PhD
[Glasgow School of Art]

ABSTRACT

Bangalore is one of the fastest urbanizing cities in India due to rapid increase in population and migration of people from varied and distinct cultural backgrounds. This has resulted in rapid development of high density housing characterized by towers of repetitive units. Most modern housing developments are focused on the repetition of units suitable for an average dweller, without taking into consideration the diverse and dynamic needs and wants of individuals and society.

What is ironic is that for centuries now, most societies have produced housing it requires, naturally and indigenously. The traditional vernacular architecture has always been in empathy with the environment.

This project develops options for a prototype housing unit and tests it by an analysis using the TAS software package for achieving flexibility without compromising on natural ventilation. It then develops a residential cluster which can be used as a model for future developments in Bangalore.

INTRODUCTION

India is urbanizing at an unprecedented rate due to an immense increase in population and migration of people from distinct cultural backgrounds and traditions from the suburbs and villages into cities. This has resulted in rapid high density housing development in the city resulting in towers of repetitive units. Migration has given rise to more mixed-cultural societies. These residents from varied cultural backgrounds and traditions, therefore, require residential areas or spatial configurations of apartments to be adaptable, comfortable and culture friendly for a better living. This cultural heterogeneity demands a different approach to housing. Also, the current housing industry is very limited when it comes to catering for long term social needs. It is crucial to take into consideration the different needs and patterns of individuals or each family.

While traditionally most buildings fundamentally responded to the climate, in the recent times, the dependence on mechanical heating and cooling devices has increased immensely, bringing about a change in the housing form and also the lifestyle of the people. Energy consumption in the building sector alone is more than one-third of the national energy use in India (Plea, 2013).

In architect Charles Correa's words:

"In a third world country like India, we simply cannot afford to squander the kind of resources required to air-condition a glass-tower under a tropical sun." (Correa, 2012, p.21)

India being home to diverse climatic conditions and energy availability being scarce it is important that buildings use passive means rather than mechanical air conditioning and heating. The term 'passive' refers to those design techniques which, in order to enhance thermal comfort, utilize the favourable and

Archana Narendran is a master's student at the Glasgow School of Art, UK. Dr. Filbert Musau is a professor at the Glasgow School of Art, UK.

minimize the unfavourable elements of the local climate.

This project aims at developing a prototype for urban high-density mass housing to accommodate passive design features while providing flexibility in design to cater to the varying cultural backgrounds of the migrant population in Bangalore and assessing it using TAS software package.

The objective is to develop a flexible unit to suit the demographics and the changing family needs. The current housing industry is very limited when it comes to catering for long term social needs. It is crucial to take into consideration the different needs and patterns of individuals or each family. Currently most mass housing in the city are being taken up by commercial real estate developers resulting in high rise structures with repetitive units.

CONTEXT

Bangalore, situated in the south of India, is the third most populous city in the country with a population of 8.4 million. It is located at 12.97°N 77.56°E with an average elevation of 920m on the Deccan Plateau.

The climate of the district is classed as the seasonally dry tropical savanna climate. Bangalore experiences a pleasant climatic condition, with occasional heat waves during the summer. In summer the temperature goes up to 38°C during the day and falls to 20°C at night. In winter the maximum temperature goes up to 27°C during the day and goes below 17°C during the night (Pib, 2008). The primary wind direction in Bangalore is south-west. During the months between January and March and October and December the wind direction is from north-east to south –west and between April and September it is from south-west to north-east.

The design criteria in this zone are to reduce heat gain by providing shading, and to promote heat loss by ventilation. Bangalore being located on a relatively higher altitude experiences a pleasant climate and does not require mechanical cooling for most part of the year. Effective ventilation and air circulation can cut down the energy needs in the city.

The city, earlier, known as the “Pensioner’s paradise” is now India’s Silicon Valley with the unprecedented rapid growth caused by the boom of the Information Technology sector. Also, various MNCs have set up their R&D centres in Bangalore, attracting young professionals in search of career or entrepreneurship (Forbes India, 2014).

As a result of the migration from other cities and town, the demand for housing has really gone up in the city, mostly in the rental market. Bangalore witnessed the launch of 35,000 residential units in the year 2012 and nearly 8,100 in the first quarter of the year 2013 (The Hindu, 2013). However, the current housing developments follow a trend of “cloning”, where the developments are focused on the repetition of units suitable for an average dweller, without taking into consideration the diverse and dynamic needs and wants of individuals and society.

The potential occupants of the residences mostly being young professionals migrating from other cities, an ideal solution would be to incorporate flexibility in the planning to suit the different lifestyles and also provide for incremental growth in the housing. Also, the demand for rental properties being high, flexibility in the planning would help cater to a diverse crowd. For instance, the potential residents may vary from a group of individuals sharing a unit to a newly married couple or a growing family.

Living Arrangement in India

The living arrangement in India traditionally has been a multigenerational household where it is the duty of the child, especially the male, to provide parental support in their old age. Nowadays the shift in the demographics such as migration for employment has resulted in children leaving the residences shared with their parents and has resulted in many nuclear families in the city.

For instance, 73.6% of the household in this state are working couples and these young working populations mostly take up studio apartments as a temporary base and move out to a bigger place after a few years when the family expands or when the elderly parents move in with them.

Figure 1 Living Arrangement in India (Source: Authors)

In Bangalore, in the past few decades, it has mostly been plotted developments where people buy the land and develop their house according to their requirements.

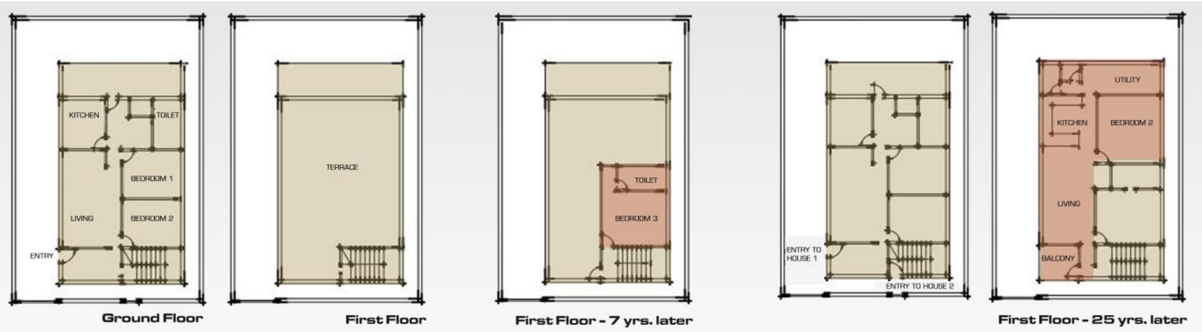

Figure 2 Example of a plotted development (Source: Authors)

Site

The site measures 1.6 acres and is located in South Bangalore, situated off Bannerghatta Main road, on Ranka Colony Road. Ranka Colony Road is developing to be one of the busiest roads, connecting Bannerghatta road to rest of South Bangalore.

Figure 3 Site Location and surroundings (Source: Authors)

DESIGN

Concept

The design attempts to bring together flexibility and passive design strategies in a prototype housing unit providing for expansion and division within a mass housing to suit the Indian living patterns. The design comprises of group housing with set defined boundaries for each housing unit.

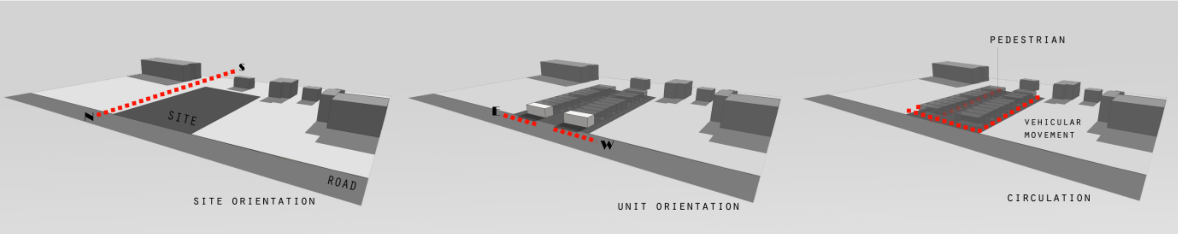

Figure 4 Orientation (Source: Authors)

The basic form was developed based on certain passive design strategies suitable for the tropical savanna climate of Bangalore.

- Orienting the longer façade in the North-South direction as east and west façade receive higher intensity of solar radiation throughout the year.
- Shading the east and west façade by staggering the units.
- Facilitating stack effect, which is very effective in the Bangalore climate.
- Taking advantage of the predominant wind originating from the east and west direction by having more openings in that direction, maximizing cross ventilation
- Possibility for controlled adjustable shading on the east and west façade.

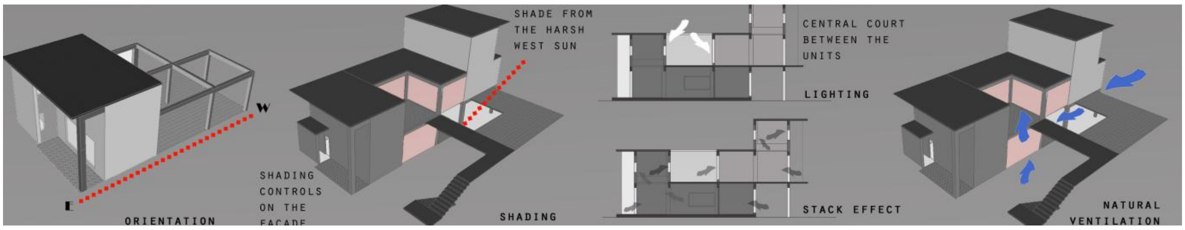

Figure 5 Passive Design Strategies (Source: Authors)

The concept of flexibility has been worked upon based on the ideology of providing a framework and giving indication to the possibilities of spatial arrangements. Initially, all units have the same basic essential form along with a steel frame structure for future expansion. The frame structure sets the boundary of the unit and gives the occupants the freedom to expand at their convenience and also to decide the materials for the infill. When it is just a basic unit, the open spaces enclosed by the frame, serve as a garden space or a backyard for the house. The framed structure forms a grid plan allowing the occupants to construct anywhere along the grid forming arrangements to suit their requirements. The planning has been done in such a way that each unit has its own court and once the unit is fully expanded, it encloses the court.

Also, two units have been interlocked together to develop a pattern of massing to achieve high density housing. At the same time, the upper unit shades the lower one from the harsh west sun. Also, the arrangement provides for unblocked cross ventilation as shown in figure 5.

In the case of a contraction in the family size, there is the possibility of dividing a single unit into two small units which can be used as an office space or a studio apartment.

The frame structure defines the boundary for each unit providing three grids for future expansion with the fourth grid serving as an open court all throughout.

Also, the units have fixed entries, even upon division.

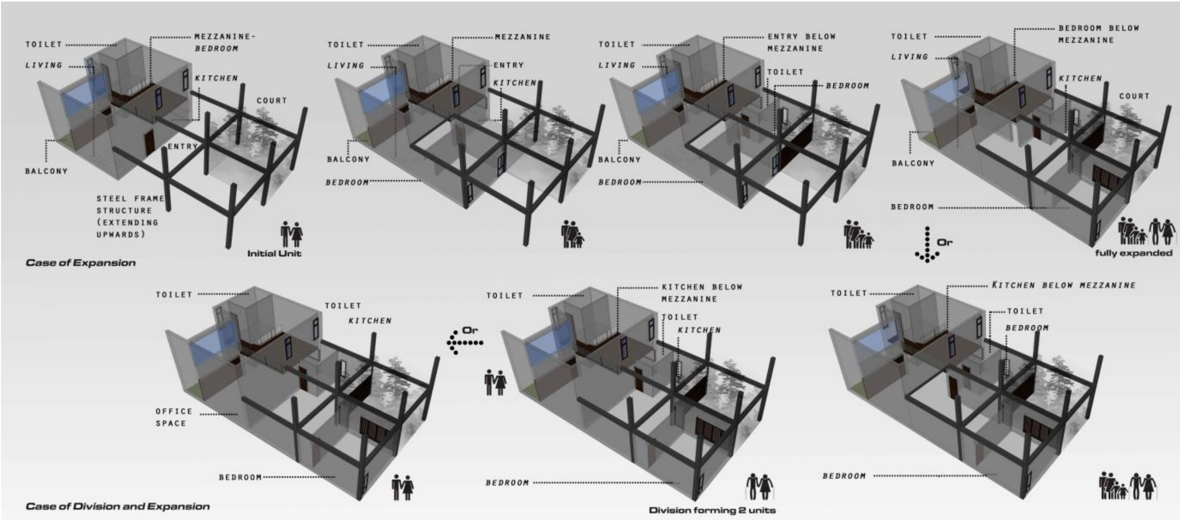

Figure 6 Cases of Expansion and Division (Source: Authors)

The above image shows the possibilities of arrangement as the unit expands. The first is the basic unit with a kitchenette space and a toilet and a mezzanine space which can be used as a bedroom. This would suit a single occupant or a couple.

As the family expands and requires more space, the unit can be expanded by constructing along the grid as seen in the second, third and fourth case where the unit can be transformed from a studio apartment to a three bedroom housing unit.

However, if the family contracts, for instance, the children move out and the elderly parents are the only occupants of the unit and they do not require so much of space, the unit can then be divided into two. This can be done by constructing a wall between the basic unit and the expanded wing forming two units with separate entries.

Massing

The massing in this context has been worked out along a central pedestrian pathway with the interlocking housing units on either side, while the vehicular movement has been restricted to the periphery. Also, the units on either sides of the central path have been staggered to maintain privacy in all the units.

The central pedestrian route opens up to several shared courts which lead on to the private courts of the housing units.

The prototype units can be arranged to form different types of massing ranging from row housing to low-rise apartments and high rise apartments where there is a space constraint.

PASSIVE DESIGN STRATEGIES AND ANALYSIS

TAS software

The software is split into three main programs, the 3d Modeller, Building Simulator and Results Viewer. As the first step, the 3d modeller is used to create the building model for simulation. Here, the different spaces are assigned different zones.

Next, the model created is exported to the building simulator. In this program, the building components are assigned its materials. Using this program, one can choose which apertures are open, when and by how much. The internal conditions are assigned for the different zones depending on the number of people occupying the space and considering factors such as lighting, etc.

Once all the information has been entered, the model is exported to the result viewer. Here, any number of parameters such as relative humidity, dry bulb temperature, etc. from any number of zones or surfaces can be displayed and compared in a tabular and graphical format.

Parameters considered:

Materials

External and Internal wall – Brick wall
Floor Slab – Concrete
Window frame – wood 50mm width

Aperture type and schedule

The stack windows in the double height space were considered to be open all through the day. The windows in the main living room were kept open during the day from 7:00 to 10:00 and in the evening from 17:00 to 19:00. The bedroom windows were considered to be open during the night from 18:00 to 07:00.

Finally, in the Result Viewer the dry bulb temperature for all the zones were compared to study if it was within the comfort range. This was repeated for the different stages of flexibility.

Comfort Range

For all climate and building types, the National Building Code of India specifies the use of two narrow ranges of temperature: summer (23–26 °C) and winter (21–23 °C), (BEE, 2005). These standards are based on ASHRAE standards, which are not validated through empirical studies on local subjects. However, India experiences diverse climates, thus it is not proper to define a single comfortable temperature for the entire country, as it would vary region wise.

Based upon a comfort survey conducted all over the world, a relation has been derived between comfort temperature (Tc) and outdoor temperature (T0) [3] as

$Tc = 12.1+0.53T0$.

Another relation was obtained for Pakistan which has almost similar climatic conditions as in India as

$Tc = 17.0+0.38T0$.

Where,

Tc is comfort temperature and T0, mean monthly maximum and minimum external temperature. (Chandel and Aggarwal, 2012)

Based on this relation, the comfort range for Bangalore for the month of May was calculated to be 26°C - 29°C and 24°C - 28°C for December.

The analysis has been carried out based on both the comfort ranges, the one based on the ASHRAE standards and the one derived from the equation.

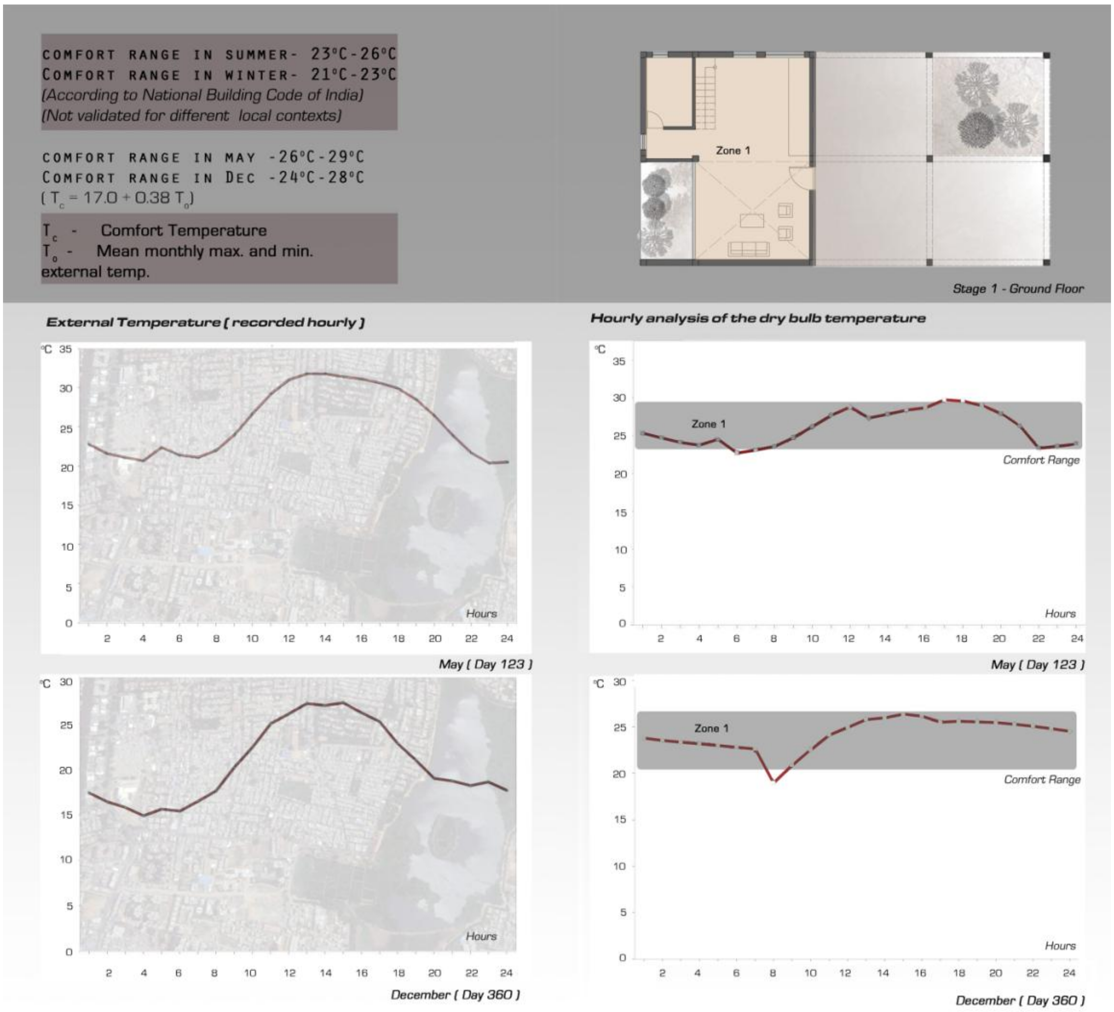

Figure 7 Variation in dry bulb temperature in a basic unit (Source: Authors)

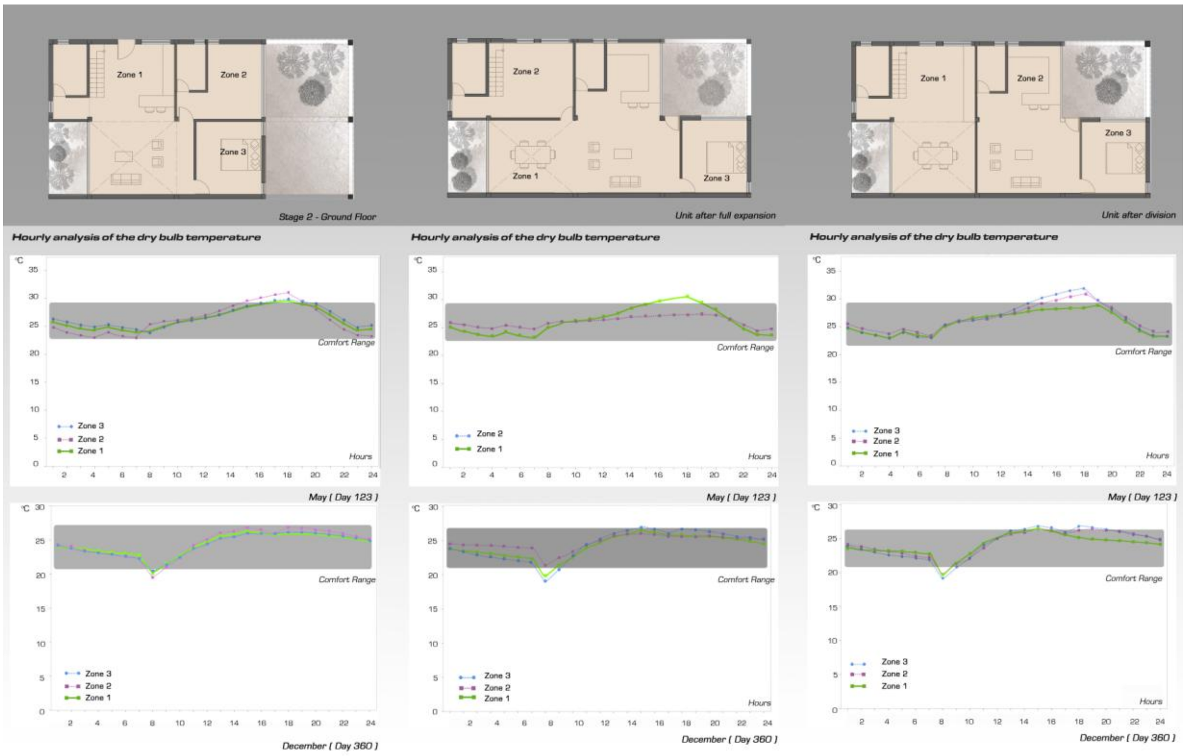

Figure 8 Variation in dry bulb temperature after expansion and division

Design iterations

First, the basic unit was simulated and it was observed that the double height space helped reduce the dry temperature within. However, it was more effective when the outlets where at the highest point and the inlets were narrow. From a comparison of the dry bulb temperature of the internal zones, it was observed that the temperature in the mezzanine was always maintained at a higher level making it an ideal zone for winter time.

Also, it was observed that the temperature within reduced with the addition of a covered balcony on the west façade. And as the housing unit expanded, the temperatures in the rooms were maintained within the comfort range when the central portion of the unit was left open with no partitions.

CONCLUSION

In a country like India, the cultural heterogeneity and the changing living patterns demands a flexible approach to housing. Also, energy consumption in the building sector alone is more than one-third of the national energy use in India. India being home to diverse climatic conditions and energy availability being scarce it is important that buildings use passive means rather than mechanical air conditioning and heating.

In terms of the factors contributing to the success of a flexible housing, most often a combination of both use and technology prove to be more effective as seen from the case studies. When the method of flexibility is just confined to the interior of an existing shell, the amount of choice and control of the occupants get limited. From the scale of a single housing unit to mass housing, with careful consideration of use and technology without much additional costs and over complicated technological systems, flexibility can be achieved successfully.

Coming down to the project, in a climate like Bangalore's with careful planning and by adopting climate responsive strategies, the energy use in the residential sector can be cut down drastically. It is evident from the TAS energy modelling analysis that the indoor temperature can be maintained to suit the comfort of the occupants without depending on mechanical cooling systems.

In terms of flexibility, the frame structure defines a boundary for each of the unit allowing it to expand or contract without affecting the neighbouring units much. Also the prototype design of the unit can be adopted to develop a variety of housing types such as row housing, high rise or even just a group of four houses.

A BRIEF REVIEW

Designing Climate Responsive residences in the composite zone of Northern India as a means to conserve natural resources

The climate of the plains of northern India is characterized by harsh summers and extremely cold winters which results in buildings being air conditioned all year round, a colossal waste of energy, adds to the carbon footprint. This paper is based on the research and construction of a prototype of a small residence constructed with the object of developing a building vocabulary of materials and techniques which cater to the contemporary tastes yet derives its roots from the vernacular architecture of the place.

As 90% of the construction in rapidly urbanizing smaller towns of India is 'individual homes' it is important to develop/construct a model or sample of a 'shelter' that is affordable, comfortable, aesthetical, functional and eco-friendly.

The architect spent over four years in developing this prototype and the paper will elucidate the solar passive design techniques and the material selection and construction methodology that has gone into the construction of this 'home' which has dispensed with the need for air-conditioning and also used eco-friendly materials in a place like the NCR. The results monitored in this cottage showed 28 degree Centigrade ambient inside temperature in the month of June when the outside temperature was 40 degrees.

A truly revolutionary concept, that needs to be popularized.

INTRODUCTION

Construction Industry is the largest growing sector in the Indian economy and is also responsible for a heavy depletion of our natural resources, from timber in building, to coal in burning bricks in kilns, to oil in transportation and mostly in the production of cement and steel. Our buildings need to be designed in response to the climate and with regard to the environment. If 90% of the buildings are for residential purposes, does that imply *"Our homes are destroying our environment?"*

Design leads to manifestation of human intention. What we make with our hands must honor the earth, and they must not only rise from the ground but return to it, without causing any harm to any living system. This is ecology, this is good design.

Are we aware that more than 80% of our construction activities cater to less than 5% of our population? That an average house for a single family uses 8 times the cement needed for its stability?

INTENT AND OBJECTIVES OF APPLIED RESEARCH

Our firm, Imarat, has been committed to building green for a number of years now, using **solar passive design** and **eco-friendly material**. It has been our prime objective to **bring good architecture to the door step of the common man**– which needs designing costeffective homes, that are aesthetical & provide all modern day conveniences. As the vernacular architecture of the Indo- Ganges plains offers very valuable lessons in terms of planning & material, it was imperative to combine traditional wisdom with contemporary necessities.

Objectives:

1. To develop a building vocabulary of materials and techniques which caters to contemporary tastes, yet derives its roots from the **vernacular architecture** of the place.
2. To incorporate the wisdom of vaastu-shastra (the ancient Indian text on building design and construction) with the principles of climatology.
3. To build our basic structure, an average home that blends with nature, while maintaining its unique sculptural beauty and aesthetics.
4. To use and promote construction material and technology which is environment friendly and locally available.
5. To develop a module/sample of a shelter that is affordable, comfortable, aesthetical functional and ecofriendly.

PROCESS/APPROACH

Site Analysis

The site is in a mango orchard in agricultural fields on the outskirts of Karnal.

1. Topography (Site Profile): The plot is in a mango orchard in agriculture land, the design is site responsive with fields on one side.
2. Climatic condition: The climate of Karnal is monsoon-influenced humid subtropical climate with high variation between summer and winter temperatures and precipitation. It has relatively dry winters and has a prolonged spell of very hot weather.
3. Maximum temperature of the city reaches up to 48°C in summers and minimum temperature in winter season falls down to 1°C. January is the coldest month with average minimum temperature of 7°C.
4. Rainfall: The annual rainfall of the Karnal is recorded to be about 600mm. Rainfall is unevenly distributed and decreases from south east to southwest. Rainy season starts by July and ends in September. About 80% of the total rainfall is received during this period. Some amount of rainfall is received from western disturbances during the winter season.
5. Wind Flow: It is influenced by southwest monsoon winds in the summer and westerly and northwesterly winds during the winter. The wind direction is NW and SE.
6. Population: Karnal metropolitan area has a population of 3, 03,425 persons. The district has a population density of 598 inhabitants per square kilometer.

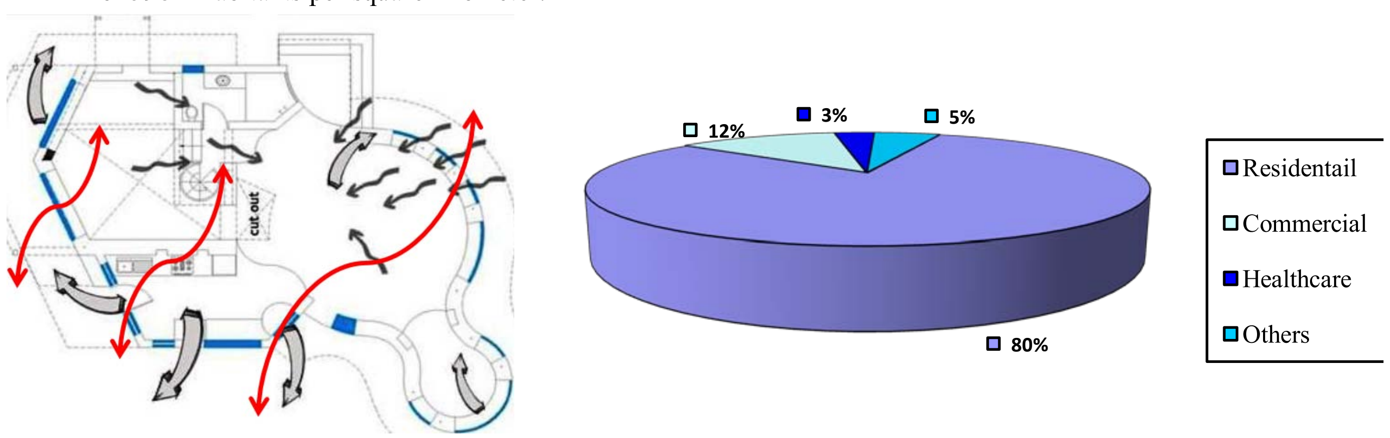

Figure 1→ (a) Wind Flowinside the building (b) Population Distribution

Design Development

The overall form of the building was detailed by the trees on site. No tree was felled – rather, the building was designed to fit in the open space between trees. The flowing curves of the building meander between the trees and the building height was kept lower than average height of a tree i.e. 17’.The built structure looks a part of its surrounding, merging in the natural grove. The basic plan is designed with the principles ofsolar passive planning.

Figure 2→MaatiSirjana merging into the setting (View from the North East)

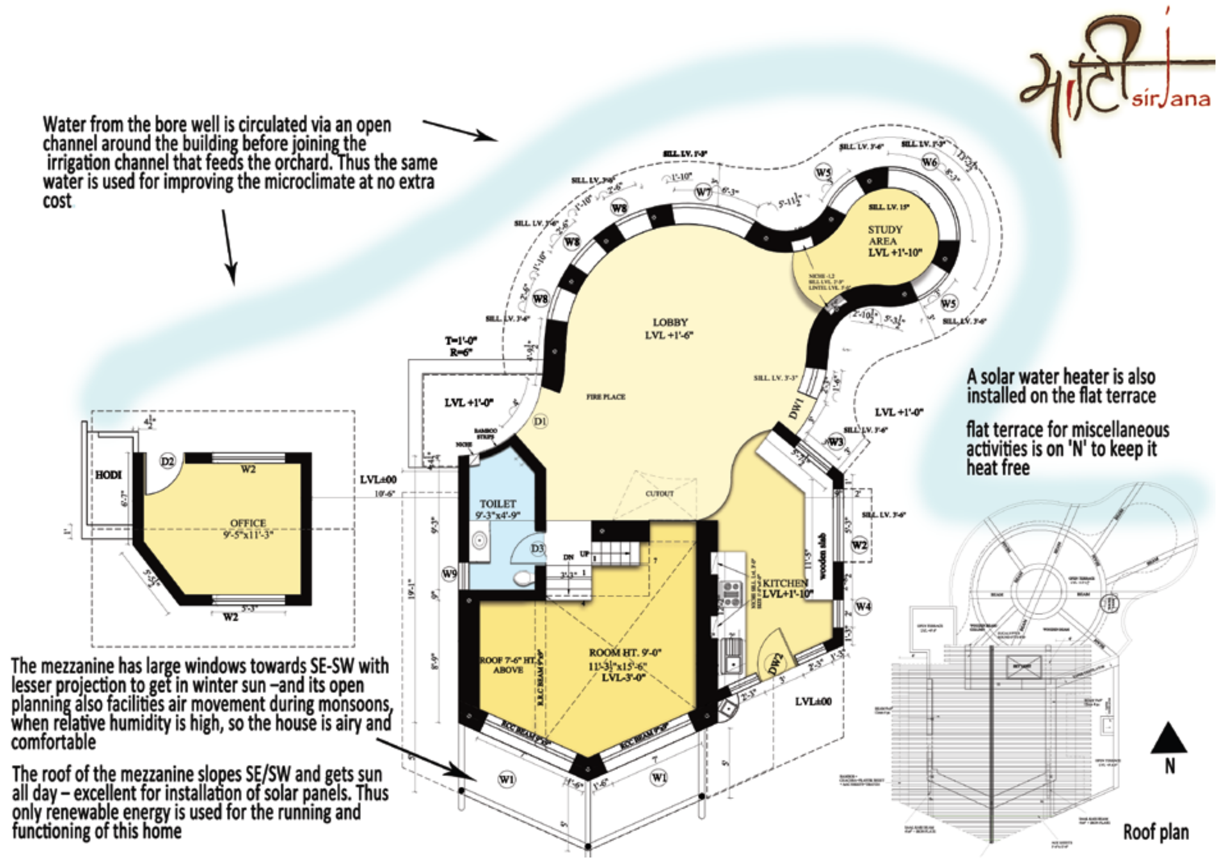

Figure 3 →Floor Plan of MaatiSirjana

Table 1. Advnatages of Space Positioning

Space	Direction/Position	Advantage
Prayer Area	North East	Gets early morning sun
Kitchen	South East	Gets natural light all day and gets morning sun-rays which act as a disinfectant.
Main Bedroom	3’ below ground level	Earth Cooling
Bathrooms	Stacked above one another	Easy Plumbing
	In the West	Traps the heat from the afternoon sun in summer and prevents heating up of rooms.
Windows (Large)	North	Gives heat –free / glare free light
Lobby (Open to the sky)	Center of the building	Improves the energy flow within the building and also cools it in summers
	Openable skylight	Acts as a duct for evaporative cooling in extreme heat and improves air circulation and wind flow.

Materials and Construction

This project showcases the techniques of constructing in mud, bamboo, thatch, terracotta and burnt brick. The age-old techniques have been refined and improvised so as to ensure **longevity, ease of maintenance, cost effectiveness, contemporary demandsviz-a-viz aesthetics and comfort**A lot of research and improvisation was done to reach an optimum solution. The ancient science of vaastu viewed buildings as a whole with man and environment.

Adobe: The typical adobe wall is built on the top of a foundation of concrete block, or stone and mortar, which rises high enough above ground level to eliminate the erosional action of standing water. The tar can be used as a moisture barrier between the concrete block and adobe.A concrete bond beam formed on the top of the last course of adobe ties the wall togethor and supports the roof framing. This works well in moderate and hot climates. Builders of energy–efficent homes often augment these thermal qulities with insulation, particularly in cold climates. Some adobe walls are left exposed, and deep overhangs protect them from moisture.

Construction

The foundation upto plinth level was done in burnt brick. Two steel bars 8mm were used in the plinth beam and junctions to ensure seismic resistance. Also the burnt brick plinth prevents the harmful effect of ground moisture on adobe. During the construction of the foundation, the mud bricks were being made on site by earth dug out. This eliminated the requirement for fuel for transport. Burnt bricks have been used only up to plinth and in service areas as this ensures better plumbing and results in contemporary washrooms –a necessity with the modern–day users.

The structural strength of mud bricks and burnt bricks is carefully utilized with due preference given to the former as they are more sustainable and less energy intensive. Reinforced concrete bands are run above openings as well as plinth to ensure seismic- resistant safety. The structural safety is ensured, while working towards reducing the carbon footprint of the building. For the main lobby area terracotta filler slab is used as it more cost effective and provides better insulation.

A detailed study of the vernacular architecture revealed that the grass grown along the irrigation canal could be used for roofing. This particular weed grass*sarkanda*(Saccharumbengalense) is insect resistant and fire resistant, however, over a period of time, as RCC roof slabs became the norm, the techniques of thatch roofing were hard to find. An extra layer was added for the water proofing, between two layers of thatch. The local labour was thus trained for future use. Not only does the roof cost much lesser, its thermal insulation is far superior and no transport of material was necessary.

Sal rafters, recycled and bought from old homes (being demolished in various parts of the city) are used for the mezzanine floor.All the furniture, fitting, accessories were crafted on site from the waste wood of naturally felled trees on the site. Thus no new wood was used. However 150 new trees were planned in the vicinity to maintain the regenerative process. The plastering of the mud wall has been done in straw, mud, cow dung and adhesive. The resultant wall looks like heritage paint and gives a serene effect. Change in the quality of daylight across seasons makes the experience of mud–plastered walls dynamic. Light may reveal their texture in sharp relief or a mellow tone. As there is a potters village nearby, handmade tiles from the local potters are used in the kitchen and bathrooms. The deck was made out of local eucalyptus and sal wood rafters with bamboo railing. Flooring in mud is done in the living area. Linseed khal was used with mud, clay, cow dung, straw. When rubbed thoroughly it gives a shining mud finish, an excellent floor. Bamboo is used for ceiling treatment, railing and light fixtures.

The underground room and kitchen flooring is in the local "katni" stone Keeping the current day necessity of security, a state of art security system is installed. There is also an inverter power backup and a duct for a desert cooler that cools the entire house at very little cost. All services i.e. electrical, sanitary are by green certified companies –Thus ensuring –***A fusion of traditional techniques and materials with modern necessities.***

OUTCOMES

The house has been in use for a year and half and has seen all season of the Indo-gangetic plains of North India from very severe summers,to heavy rainfall, to extremely cold winters. Just one desert cooler,with a vent through the central duct was sufficient in summers. In June when the temperature outside was 45°C, inside it was 28°C – perfect for human comfort. In winters, the in built fire place was used to burn scrap wood collected from the grove and the temperature inside was 22°C, where outside was 13°C. Openable windows ensured perfect cross–ventilation, trapping the breeze in monsoons and creating Venturi effect, thereby adding to the human comfort.

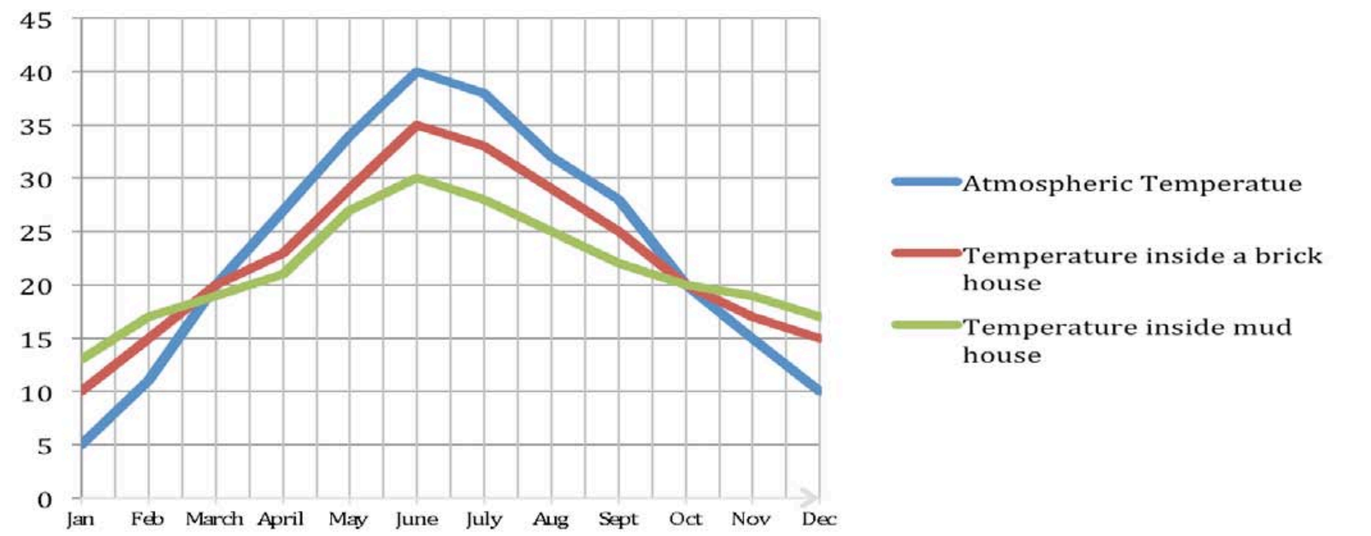

Figure 4 → Graph Showing temperature emulation

Adobe has excellent thermal insulation and accoustical properties. It also filters out harmful radiations and is low cost – ecologically and economically. A house planned according to the solar passive techniques, principle of Vaastu and built in adobe, thatch and filler slab is cost effective and ensures human comfortwithout consuming extra energy.

INFERENCES AND CONCLUSION

We cannot ecologically afford 6-8 air conditioners or the tonnes of steel and cement that go into building an average home when thousands have to be built. Operating on a 12 hour cycle of passive cooling and solar heating, adobe dramatically reduces the reliance on air-conditioning units. In a time of volatile fossil fuel prices, the economic benefits of adobe's natural temperature controls are difficult to ignore.

Smaller towns like Karnal in India, are unbanizing at a great pace, and each individual aspires to own a house. It is estimated that the residential sector in construction is likely to see an unprecedented growth.

If architects and builders were to provide homes like *MaatiSirjana*we could reduce the carbon footprint in this country significantly. Building in mud is seen as building for the poor, if awareness is generated – it could change the mindsets of people in a developing country like India. By reducing a home's environmental footprint a homeowner can lower operating costs. The owner will enjoy increased comfort due to fewer drafts, better humidity control and better indoor air quality, and will benefit from enhanced durability and less maintenance based on the longer-lived components and systems utilized.

T.E.R.I. Testimonial The Energy Research Institute, Delhi has introduced GRIHA, a rating system to judge the "greenness "of building.Swagriha**:** Is the system in which building with covered area less than 2500 sqm is evaluated.

*MaatiSirjana*was submitted for the *Swagriha*rating and was approved by the evaluators. Thus it is ecofriendly, green and low cost.

A Multi-Stage Approach to Low Carbon Housing Renovations

Marianna Rosa Arpano, MSc
[Oxford Brookes University]
marianna.r.arpano@gmail.com

Paola Sassi, PhD
[Oxford Brookes University]
psassi@brookes.ac.uk

ABSTR ACT HEADING

In 2009 the European Union approved "Roadmap 2050" to reduce greenhouse gasses by at least 80% below 1990 levels by 2050. In 2012 the Danish Government established to achieve 100% autonomy from fossil fuels by 2050 by implementing a strategy that included reducing energy demand of existing housing that accounts for about 40% of the national gross energy consumption. A mass retrofit of the existing housing stock could lead to 75% reduction of energy use and carbon emissions. However due to the cost and disruption of retrofits that can radically improve energy performance of buildings, strategies that address both disruption and cost have to be considered. One such potential strategy examined in this paper is a staged approach, which involves different elements of a building to be upgraded over several years, thus spreading the capital cost of the work and enabling the occupants to remain in their homes. Applied to the Danish context this approach can also benefit from financial incentives currently in place. Adopting a case study approach in conjunction with IES modelling, a cost analysis and interviews with industry experts, this research examines the energy savings, capital cost, cost savings of a selection of energy improvements measures, and the implications of undertaking the building work on the occupants of typical Danish detached houses built between 1850-1930. It concludes by proposing a decision matrix for home owners to achieve the most cost-effective and least disruptive approach to undertaking radical energy upgrades.

INTRODUCTION

Background

In 2009 the European Union approved "Roadmap 2050" to reduce greenhouse gasses "by at least 80% below 1990 levels by 2050" (Roadmap 2050). In March 2012 the Danish Government established a new, ambitious Energy Policy, to achieve a 100% autonomy away from fossil fuels by 2050. The strategy adopted to reach such results involves a consistent reduction of the energy demand. According to the Danish Energy Policy Report (Ministry of Climate, Energy and Building, 2012), the existing building stock accounts for about 40% of the total energy consumption; more specifically in 2010 the 69% was related to the housing sector, and the 36% to non-residential buildings (IEA, n.d.; Agency Danish Energy Agency, 2011). Thus, the biggest savings could be achieved by improving the energy performance of the less efficient housing stock. However, this mass-retrofit meets two barriers, involving the government and the private owners: one is financial (Kragh and Rose, 2011, p2252) and

Marianna Rosa Arpano is a former MSc SBPD student, in the Department of Architecture, Oxford Brookes University, Oxford, UK.
Paola Sassi is a senior lecturer and program leader at Oxford Brookes University, Oxford, UK.

one is practical (Thorpe, 2010, p.2). The first requires financial help from the government to the private owners, and second one requires a solution to prevent the occupants from moving to a temporary home. A multi-stage or "stepwise" (Galiotto *et al.*, 2012) approach to energy efficient retrofits could address these issues.

Aim of the research

This paper investigated a staged retrofit strategy as feasible solution to finance a national mass retrofit; to make an expensive housing retrofit more financially sustainable and more practical. Smaller and less disruptive works carried out in several stages could distribute the total investment in more than one transaction; they could also allow the occupants to stay in their homes and avoid additional expenses to rent a temporary accommodation.

METHODS

Due to time limitations this research has focused on a specific category of detached houses, built between 1850 and 1930. Detached houses were identified as most diffused and the worst performing housing type; they account for the 52% of the entire housing stock (Statistics Denmark), and for more than 330,000 units (53%) with EPC labels between D and G and a heating consumption requirement above 240 kWh/m^2/yr (Aggerholm *et al.*, 2010)-.

The construction details and materials of the housing type analyzed were sourced from the Danish report for TABULA Project (Wittchen and Kragh, 2012). The reference retrofit measures used were collected from a previous research by SBi, the Danish Building Research Institute (Galiotto *et al.*, 2012), by VTT, the Technical Research Institute of Finland, (Häkkinen *et al*., 2012) and Larsen *et.al* (2011).

IES- VE was chosen as dynamic simulation tool to test the effect of several retrofit measures on the building performance. A 3d model of a real detached house from 1917 and located in Copenhagen was built in IES. It was used an average floor, window and floor area; average construction, materials and shape; the U-values, infiltration rate, boiler type were conformed to those specified in the TABULA project report (Wittchen and Kragh, 2012). The NCM heating, appliances and occupants' profiles were used. The details of the model created and the average building described in TABULA are shown in Table 1.

Table 1. Multi-Stage Plan. Number of Years for Each Stage.

	Average building	Example building	
U-values			Area m^2
Wall	1.6 W/m^{2}K	1.6180 W/m^{2}K	88
Roof	0.6 W/m^{2}K	0.5724 W/m^{2}K	86
Ground Floor	1.5W/m^{2}K	1.6078 W/m^{2}K	47
Windows	2.7W/m^{2}K	2.7 W/m^{2}K	15
Door		2.29 W/m^{2}K	
ACH	0.45	0.45	
Boiler	Old non condens.	Old boiler Ɛ=55%	
Fuel	Oil-gas	Oil - gas	
Area	112 m^2	122 m^2	
Windows area	15.1 m^2	15.1 m^2	
Wall area		88 m^2	
Roof area		86 m^2	
Slab		47 m^2	
Ceiling Height	2.5	2.1 (basement, first floor) 2.7 (ground floor)	
Location	DK	Copenhagen	
Age of construction	1850-1930	1917	
Heating consumption	263 kWh/m^2 yr	265 kWh/m^2 yr	

ANALYSIS

IES modelling

A first series of simulations was carried by introducing one variable at a time in the model's building construction; such as wall, slab or roof insulation, new windows, mechanical ventilation, heating system. All the measures were previously collected from other research. The results were organized in reduction of the heating consumption (%), the reduction of Carbon Emissions (%), the grade of disruptiveness and invasiveness of each measure (low- medium and high). Table 2 shows the percentages of reduction achieved by the measures belonging to the different building's systems.

Table 2. Heating Consumption (%) and CE reduction (%) of the Building's System tested in IES-VE.

Measure	Heating reduction	CE reduction
External wall insulation	51,2%	39,7%
Slab's insulation	16-20%	12-22%
Mechanical ventilation combined with airtightness of 0.15ACH	10%	7%
Windows	5-7%	4-6%
Roof and ceiling insulation	6-8%	4-5%
Heating system	0%	7%

Cost Analysis

In order to identify the most cost-effective and less invasive measures, it was important to compare the costs, the savings and their grade of disruptiveness. The comparison was carried only for wall and slab's insulation as the measures tested varied for thickness, type of material and strategy adopted (internal or external insulation).

The prices were found online, and on Spon's Architects' and Builders' Price Book 2013, available at the University's Library (Langdon, 2013). The Danish prices were available on V&S Prisdata, provided by Byggecentrum, with an annual price. For this reason, the labour prices were searched in Spon's, while the materials‘ costs were found on the sellers' websites (listed in the references), and by asking quotations to the manufacturers.

The external insulation of the wall with demolition of the cavity wall, and cavity insulation + internal insulation were excluded from the feasible measures because highly invasive and disruptive, less effective than the external insulation, and more expensive. Thus, the most cost-effective solutions with the shortest payback period are the insulation of the cavity wall and an additional external insulation, which can be between 50 and 160 mm., as shown in Fig. 2.

As shown in Fig.3 the ceiling insulation seemed to be most cost-effective than the roof insulation because it involves a smaller surface to cover, thus lower material costs, but similar savings to the roof insulation (6% reduction of heating demand in both cases, 4% reduction of CE for 200mm insulation and 5% for 400mm insulation). Also the ceiling insulation can be less disruptive than the roof insulation, which would involve a disassembly of the roof cover and waterproof layer. Such measure is suggested only in case the roof needs to be updated because it would solve a problem of thermal bridging in the junction between the roof and the external wall.

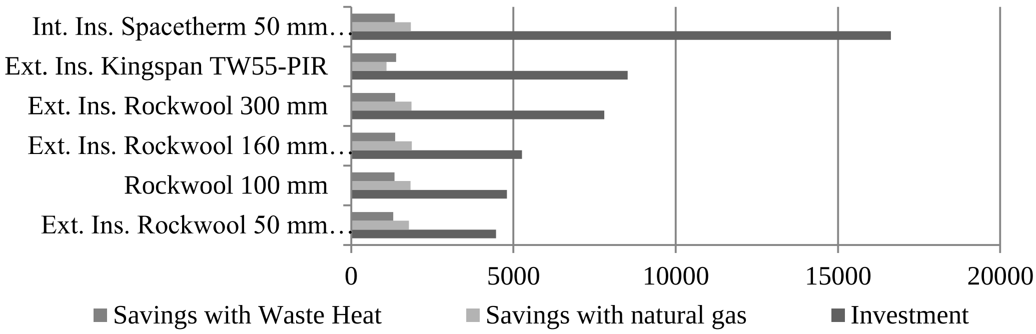

Figure 2 Investment, Saving with Waste Heat and Saving with Natural Gas for Wall Insulation Measures (£).

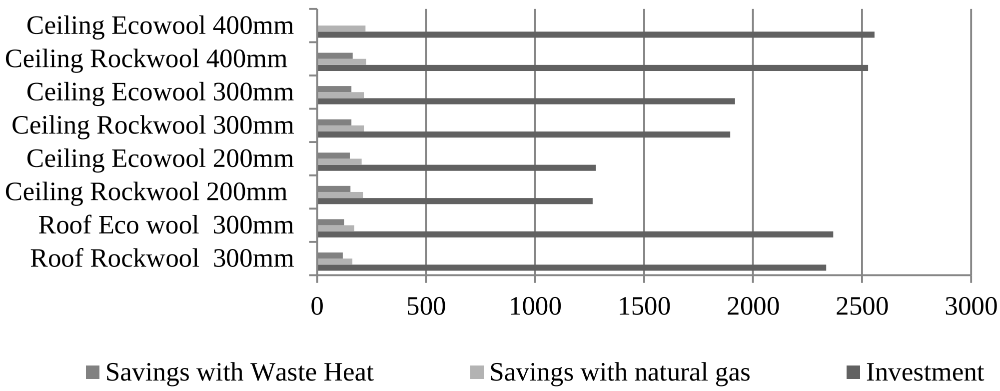

Figure 3 Investment, Saving with Waste Heat and Saving with Natural Gas for Roof and Ceiling Insulation (£).

A second series of simulations was run to estimate how much the heating demand could be reduced, once all the retrofit measures are completed. For this purpose any possible combination of measures was tested. The ACH used were 0.3 (a medium value); in such old leaky houses a value of 0.25 ACH is hardly achievable. Among 127 simulations the heating demand varied from a maximum of 39 kWh/m^2/yr, to a minimum of 20.7 kWh/m^2/yr; both results are lower than the established goal of 44 kWh/m^2/yr (Danish energy class 1).

According to the results of all the IES simulations, the multi stage plan should follow the next order: cavity insulation, external wall insulation, slab insulation, mechanical ventilation, roof and ceiling insulation, windows and heating system.

However these dynamic simulations cannot considerate the fact that the single measures are part of a staged plan and cannot preclude further works in the future (Thorpe, 2010).

Interview

For this reason a semi-structured interview was conducted with a NIRAS' engineer specialized in energy efficient retrofits. During the interview, the installation of an automatic heating control system was recommended as first measure on the list, being a cheap and very effective solution. In fact, further simulations confirmed that.

The time-temperature control and the time control can both lead to a 38% reduction in space heating demand; while the temperature control only a 10% reduction. The carbon emissions were reduced by 31% with the first two controls, and by 9% with the third one.

The engineer also evidenced how changing windows can be a priority for the occupants to enhance the thermal comfort, and avoid air-drafts.

Besides, it was suggested to consider windows and external insulation as a whole package; indeed, if the external insulation is applied first the windows should be moved to the outer layer of the wall to avoid thermal bridges. Thus, the windows could be changed when moved, avoiding extra installation costs.

At last, the mechanical ventilation cannot be considered as measure unless an airtightness test proves that the infiltration rate is lower than 1,5 ACH_{50}.

The limitations of a multi-stage retrofit were also discussed during the interview. Not all the construction details can be solved during a multi-stage retrofit (certain thermal bridges) and these limitations need to be accepted and explained to the owners not to create too high expectations. In fact, the savings obtained by large scale and less expensive retrofit (nearly 80%) can still make a big difference in reducing the gross energy consumption and the CO_2 emissions of a Country.

Multi-stage plan

Based on these suggestions and considerations the final multi-stage plan was organized in 11 stages and the measures of each stage were classified in low-medium and high budget (Table 3), The intent was to produce a flexible scheme that leaves to the single owners the choice of the best measures for their budget.

Table 3. Multi- Stage Retrofit Plan

		Low budget	Medium budget	High budget
1	Automatic heating control	Boiler control	Boiler and time/temperature control	Boiler, time and temperature control
2	Cavity insulation	75mm Phenolic foam	75mm Eco bead Platinum	75mm Bio-foam
3	Windows	Double-glazing 1.25	Double-glazing low-e	Triple glazing
4	External insulation	50mm mineral wool, EPS, PIR	100mm mineral wool, EPS, PIR	160mm mineral wool, EPS, PIR
5	Roof insulation	300mm Rock wool, Ecowool	400mm rock wool, Ecowool	Renovation of the whole roof and placement of 340-400mm insulation on the external side of the roof.
6	Basement insulation	200mm Rockwool, Ecowool, cellulose insulation	300mm Rockwool, Ecowool, cellulose insulation	400mm Rockwool, Ecowool, cellulose insulation
7	Slab insulation	160mm XPS insulation on top of the existing slab	250mm XPS insulation under the new slab	300mm XPS insulation under the new slab
8	Basement insulation	50mm insulation	100mm insulation	
9	Insulation/new external doors	50mm insulation	New insulated doors	
10	MVHR	High efficiency	Most efficient MVHR model	
11	Heating system	Gas boiler	District heating	Ground Source heat pump

The list of measures was accompanied by a scheme, shown in Fig.4, with questions and answers (yes/no) that show which is the first stage to undertake and which should follow. For each stage there is a corresponding color, that remands to the first scheme of measures.

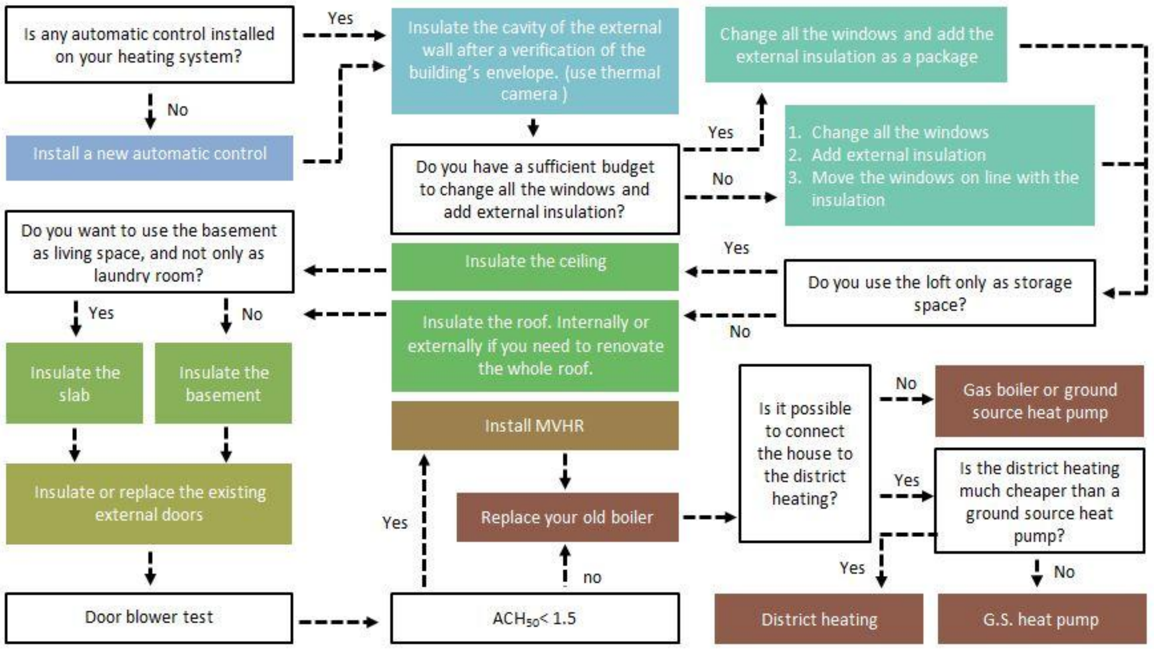

Figure 4 Guiding Scheme to House owners.

Possibilities to finance energy efficient retrofits

If the financing barrier is to be overcome, the annual cost of energy renovation investment should at least be equal to the annual savings on energy (Kragh and Rose, 2011), and at the moment, even with the increased energy price, the payback period for energy retrofits is still too long.

In this research an existing tax deduction was used to abolish or reduce the difference between investments and energy savings as shown below :

$$Annual\ Investment = Annual\ Energy\ Savings + Annual\ "Artisan\ Deduction"$$

The so called "artisan deduction" consists of about £2000 per salary/yr, to deduce for installation and craftsmen costs, but not for materials and devices costs (SKAT), which account for half of the total investment. In this research it is assumed a modification of the tax scheme, allowing the homeowners of a specific category to deduce also materials and devices' costs.

Another assumption is that the annual savings on energy are cumulated and saved in a bank account with exclusive use for the next stage, until the whole retrofit is completed.

In Denmark detached houses are often occupied by one or two families, in which case there could be two, three or four salaries that could bring £3496-£5244 of tax deduction per year/house.

A scheme showing the investment, the energy and carbon savings and the tax deduction for 1,2,3 and 4 salaries was created to verify the workability of the new "artisan deduction" and the cumulated energy savings. The final equation is:

$$Annual\ Investment = \sum_{n-1}^{n} Energy\ Savings\ + \ Artisan\ Deduction$$

n=number of the years since the first retrofit stage

Where the result is negative, the investment is paid back in the same year of realization, through the monetary savings obtained by reducing the energy demand and the incentives. When the difference is positive, the incentives and the monetary savings are lower than the initial investment. In the first case, it could be possible to carry one or more measures during the given year, depending on how much of the incentive is left. In the second case the measures too expensive to be paid in one year, should be carried out in two or more years (i.e. windows can be changed one at a time). Another solution is to wait a couple of years, save the money not spent for heating, and use it to pay in a single shot the works.

In order to estimate the number of years necessary to carry on the whole retrofit, every time the difference was negative, a new calculation was done adding the cost of the next measure and the savings achievable from that. If the difference was still negative the two or more measures could be carried out the same year.

In all cases the first two steps can be completed in one year. The window replacement can require one or two years with one salary, and one year for the other three cases. Only with four salaries per household the windows could be replaced at the same time when adding external insulation. The next steps can be completed in five years with one salary, for a total of seven years, in case the house is connected to the district heating; and twelve years if there is a heat pump. In case the salaries in the house are two, the retrofit could be completed in six-seven years. if there are three salaries four-five years could be enough to complete the retrofit; four with the district heating and five with a heat pump.

Table 1. Multi-Stage Plan. Number of Years for Each Stage.

Year of retrofit	**1 Automatic Control**	**2 Cavity Ins.**	**3 Window**	**4 Ext. Ins.**	**5 Roof Ins.**	**6 Slab**	**7 Door**	**8 MV**	**9 Boiler**	**10 Heating System**
1 salary	Yr 1	Yr 1	Yr 2-3	Yr 4	Yr 5	Yr 5	Yr 5	Yr 6	Yr 7	Yr 7-12
2 sal.	Yr 1	Yr 1	Yr 2	Yr 3	Yr 3	Yr 4	Yr 4	Yr 4	Yr 5	Yr 6-7
3 sal.	Yr 1	Yr 1	Yr 2	Yr 3	Yr 3	Yr 3	Yr 4	Yr 4	Yr 4	Yr 4-6
4 sal.	Yr 1	Yr 1	Yr 2	Yr 2	Yr 3	Yr 3	Yr 3	Yr 4	Yr 4	Yr 4-6

Incentives plan to retrofit the detached houses built between 1851 and 1931 by 2030

Supposing the national mass retrofit starts in 2015 detached houses between 1850 and 1930, all the houses with three or four salaries could be completed in 4-6 years. In 2020 the next stage of the mass retrofitting could start with the houses built between 1961-1972. By 2027 the first stage should be concluded and the 11 % of the whole Danish housing stock retrofitted (Fig.5) with 80% energy reduction. As shown in Fig.69 this group of houses accounts about the 31% of the energy used by detached houses, so the 80% reduction would be equal to 24% reduction of detached-houses' energy use.

CONCLUSIONS

This paper has investigated the possibility of using a multi-stage plan to overcome economic and practicality barriers to energy efficient housing retrofit. The research results have shown that the integration of dynamic simulations and the practical experience of specialists can lead to multi-stage retrofit plans for each housing type.

A financing scheme was proposed to equal the annual investment for retrofit, to the derived energy savings; however, a similar model would be burdensome for the national tax system; which would see the national tax income considerably reduced. On the other hand, without a significant help from the government, only a few house owners would invest their own savings in such housing retrofit, as “one of the main barriers in renovation” is “financing” (Kragh and Rose, 2011, p. 2252).

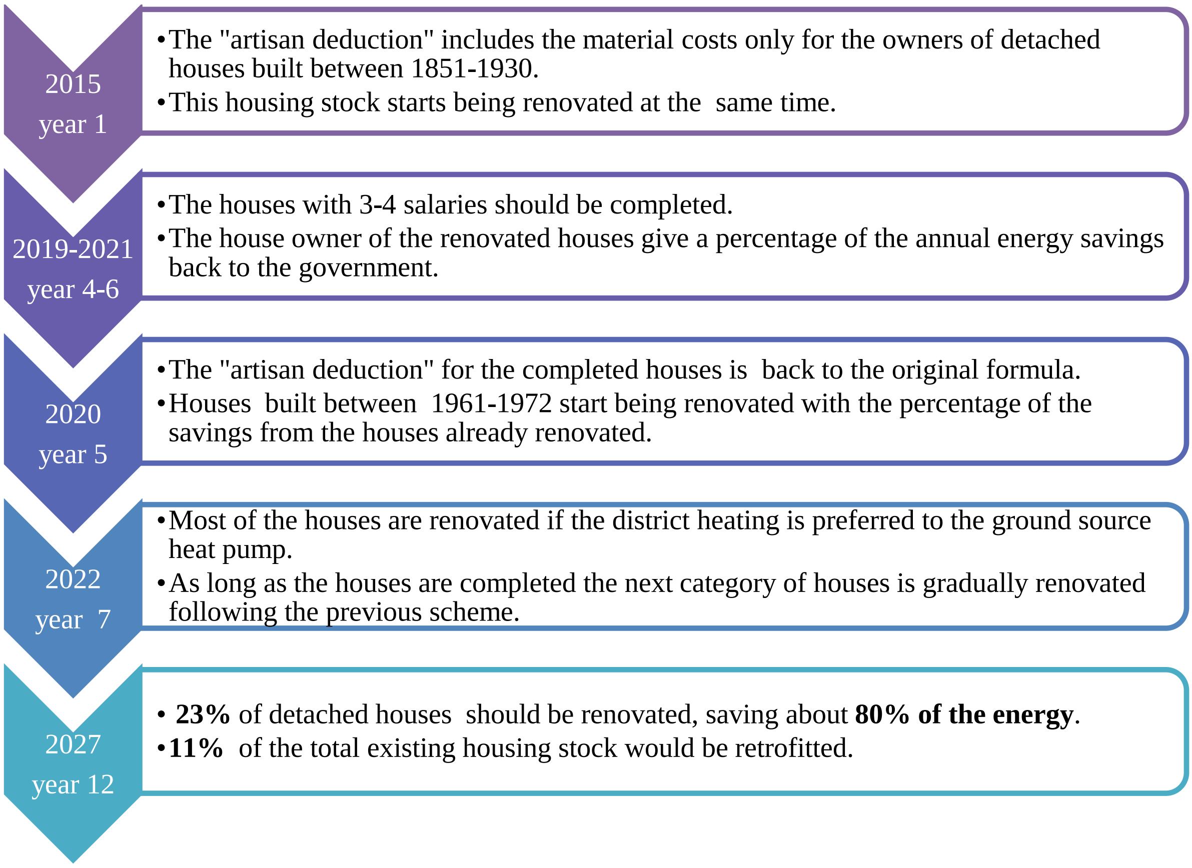

Figure 5 Sample of Mass Retrofit Organization.

Most of them would probably decide to upgrade something, not aware of what they could actually do to have an energy efficient house. In conclusion this research suggests that government guidance is essential as government funding schemes. The proposal of recouping a percentage of the monetary savings achieved by the house holders to help the government to finance the second step could make the scheme unpopular, if the advantages derived from such help are not well stated. Nevertheless, this scheme does not require any investment to the owners, which have only to pay upfront.

Educating the householders about the long term and non-monetary advantages is critical to their acceptance of the scheme. This research has shown how tax-related schemes can encourage retrofit initiatives and how technical solutions can help reduce the cash flow and capital cost. Other technical solutions and financial incentives could address these and other barriers to retrofit initiatives and should be further investigated. In addition, all incentive schemes need to be supported by effective information and this area could also benefit from further research.

ABSTRACT

The existing building stock in the United Arab Emirates finds it more difficult to compete with the new more environmental friendly and energy efficient buildings and do not fit into the country's vision of sustainability. Even if all new building have zero CO2 emissions, the older inefficient building stock will cause the CO2 emissions levels to remain unacceptably high which, means older building stock needs to adapt to environment friendly energy efficient measures. The current research focuses on the green retrofitting strategies of an existing building in the hot and arid climate of the UAE. The study examines the existing building envelope of Latifa hospital using the energy simulation software e-QUEST. Using the simulation model, the building behavior was predicted for the retrofitting strategies of thermal insulations, window to wall ratios, wind types, ventilation fans and types of HVAC system to achieve optimal retrofitting of the building.

INTRODUCTION

For the last forty years, the United Arab Emirates (UAE) has witnessed an unprecedented pace of urbanization and population growth due to rapid economic development. The rapid growth of UAE's economy has been accompanied by a substantial increase in energy consumption. Partly, the significant increase in energy consumption is due to inefficient existing facilities (Elgendy, 2010a, 2010b). The UAE energy intensive construction approach coupled with its extreme hot climate , require heavy cooling and have appointed the UAE in the top 10 countries in terms of electricity usage per capita and the second highest in terms of CO2 emissions per capita (AlNaqbi et al, 2012a, 2012b, AlAwadhi, 2013). The single largest contribution to the electrical load comes from cooling which accounts for an average of 40% of total year around electrical load and up to 60% of the peak electrical load during the summer time (Al Awadhi, 2013). The majorities of UAE buildings stock was constructed long before the introduction to sustainability codes and standards and therefore is incompatible with current standards or the expectations of the users (Shady, 2010). Sustainable retrofit is not a new concept but is gaining recognition and importance owing to current concerns about intensive energy use in buildings leading to climate change (Backer, 2009).

Latifa Hospital (previously Al Wasl Hospital), a 367-bed specialized maternity and paediatric hospital, opened in 1986. The two-story hospital building is oriented east south-east (Figure1) and has a gross floor area of approximately 73,213 sq.m with the central plant area being around approximately 3,300 sq.m (Figures 2, 3).

Author 1 is a Professor, Author 2 is an Assistant Professor and Author 3 is a Master Student at the Department of Architectural Engineering, United Arab Emirates Univeristy, Al Ain, UAE .

Figure 1: *Case study; Latifa Hospital: Massing and Orientation*

The building has a reinforced concrete structural frame with foundations on piles and block work for the external envelope and internal partitions. The base structural bays are 7.20m x 7.20m for a 4.5 floor-to-floor height. Ceilings are set at 3 meters, except in wet areas where they are at a standard 2.70 meters. The external walls are made of a double block work with a 40 mm cavity filled with a pre-compressed isolation polystyrene board and a layer of bituminized fiber for dampproofing. The windows and doors are provided with sealed double glass with solar control coating to regulate the UV light and reduce heat gain while providing sufficient and uniform daylight. Double glazing windows are the common hospital window type, solar control reflective insulating glass type, and bronze color, 6 mm. with direct transmittance 21%, total solar transmittance 26%; shading coefficient 0.30% and U value 1.4 w/m2. K.

METHODOLOGY

In order to develop effective energy conservation guidelines, the nature and magnitude of the energy usage in the existing hospital was determined through direct collaboration with the hospital facility personnel.

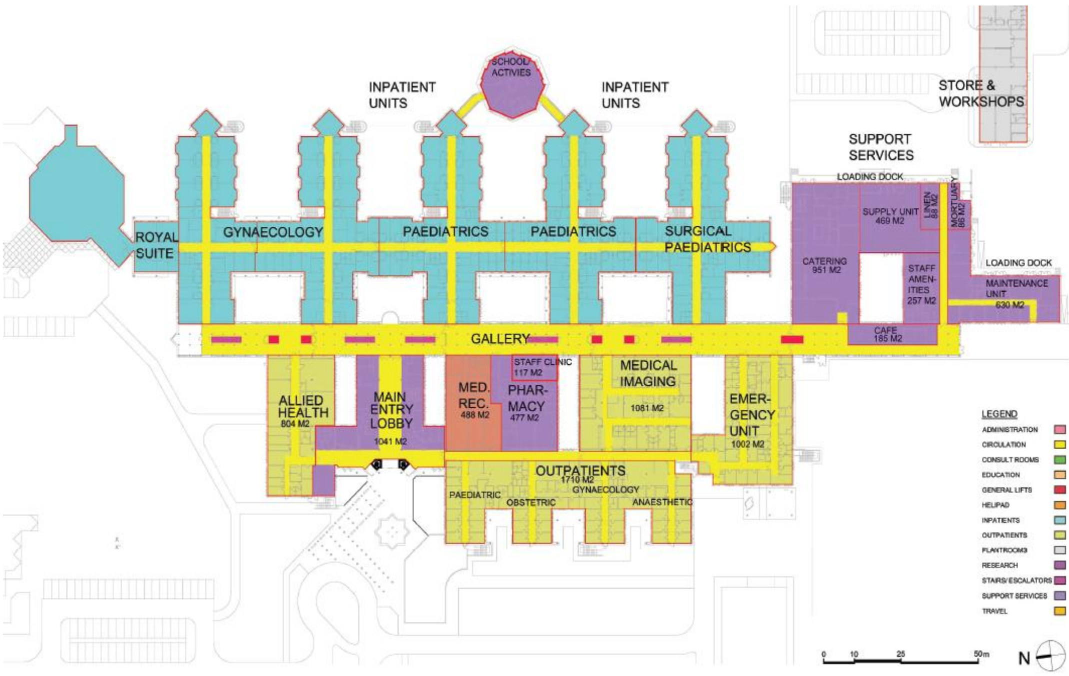

Figure 2: *Ground Floor Zones Layout*

The study investigates the performance of the existing building envelope, the HVAC system and other energy efficiency measures then explores their optimization potential. The inputs for simulation program are collected through extensive review of design drawings.

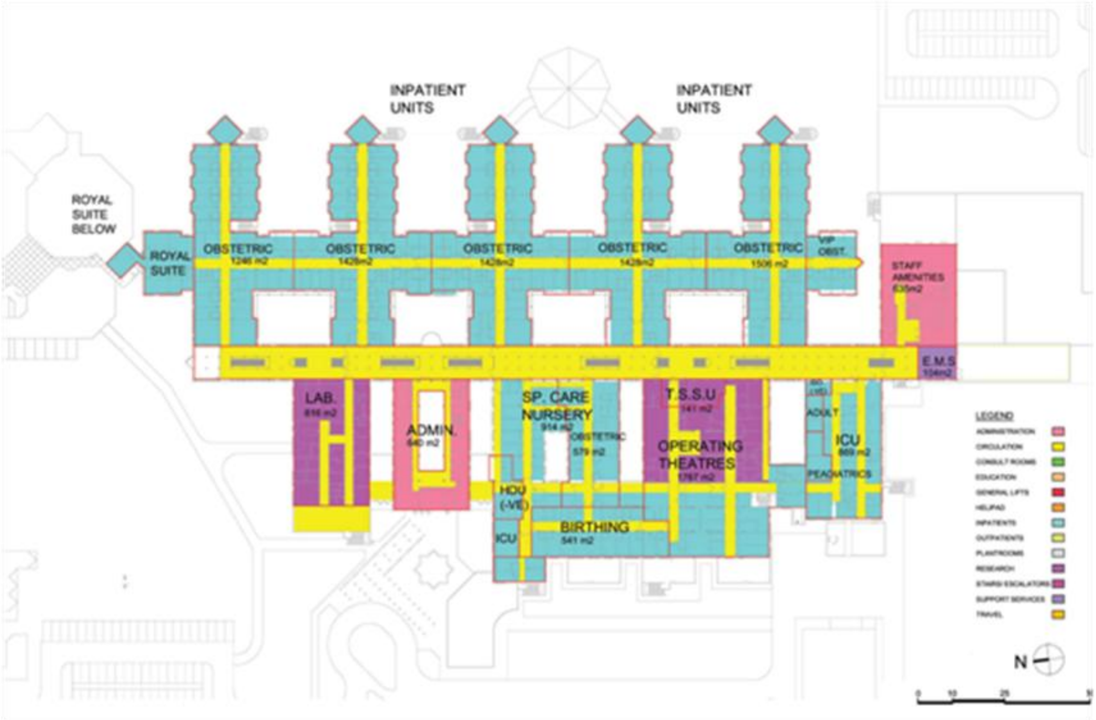

Figure 3: *First Floor Zones Layout*

All the collected data has been analyzed to determine the base case of the existing building electrical consumption and compared with the predictions of the simulations to validate the methodology. The existing building model was generated using e-QUEST software. The building was set at its actual orientation with all openings placed per their location and specificities. As a first step, the building was simulated "as is" to determine the base case. All required inputs of insulation level, type of window and glazing, shading, roof insulation, flooring construction materials, type of HVAC systems, building occupancy, operation schedules and loads were added to the program to calculate the annual energy consumption of the base case. Results obtained from the simulation (e-QUEST) software were compared with the actual energy consumption data achieved through bills and energy audit to validate the simulations results. Once the model was validated, the optimization was carried out to determine potential areas of energy savings pertinent to rerofitting.

RESULTS AND DISCUSSION

Various strategies for energy performance optimizations were tested through simulations. The energy performance simulations were performed through eQuest, in order to optimize the envelope for reduced heat gain through inulations, façade construction, envelop colour and glazings. The HVAC system was optimized for ventilation and infiltration, efficiency rating, better comfort settings and better HVAC scheduling. Thereafter based on the results and analysis, recommendations for retrofitting the building are outlined for façade construction and systems integration.

Wall Optimization

At first, the wall colour was studied for its impact on energy performance of the building to attain an optimum wall colour with reasonable energy performance assuming the darker colour as a reference and with no insulation applied. ~~Walls~~ colors were changed from dark abs.=0.9 to light abs.= 0.4 gradually and the electrical energy consumption was computed. The result shows that change in the walls color from dark to deer' light (abs= 0.45) has reduced annual energy consumption by 0.13% (Figure 4). As a second measure, the effect of wall insulation was studied on the enrgy perfroamce while changing the insulation gradually from R= 0 to R= 12. The increased insulation yielded a reduction in annual energy consumption of 0.33%. Finally the net effect of reduced colour absorptance and increased insulation was simulated which yielded an energy saving of 0.4 %.

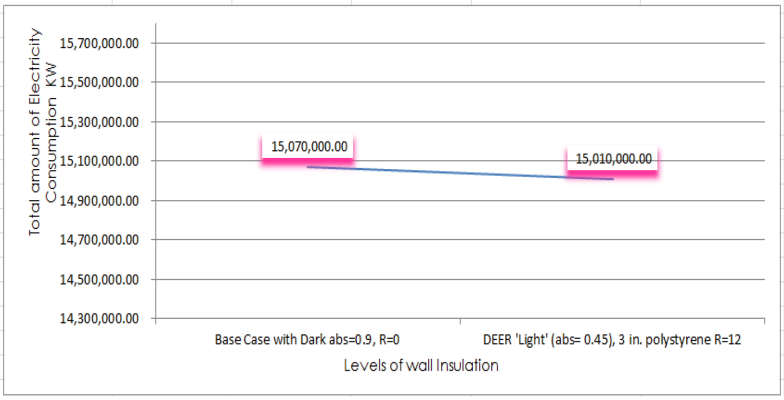

Figure 4: *Simulation results of collective wall optimization through wall colour and added insulation for Latifa Hospital, Dubai using 2013 weather data.*

Roof Optimization

The building roof was optimized following the same scheme described for wall optimization and the individual impact of color and insulation were studied at first while later the combined effect of reduced color absorptance and increased insulation were computed. Change in roof color from dark (abs.= 0.9) to deer light (abs.= 0.4) yielded a reduction in annual electrical energy consumption of 1.81 % plotted (Figure 5). It was observed that the optimum reduction of 2.59% is achieved at R=9 while the drop in energy consumption at higher R-value is insignificant.

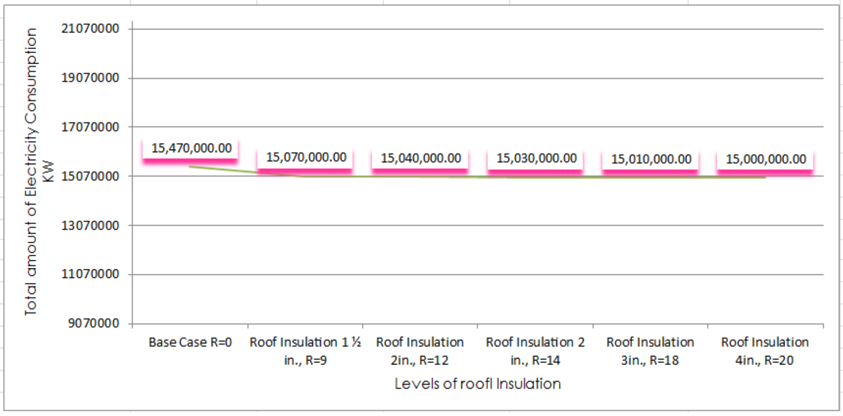

Figure 5: *Simulation results applying roof insulation for Latifa Hospital, Dubai using2013 weather data.*

Envelop Optimization

It was observed that changing the whole envelop color from dark to deer' light (abs = 0.4) yielded a reduction of 2.0% in annual energy consumption while increasing the envelop insulation from R=0 to R=9 resulted in a 3.41% decrease in annual energy consumption. Finally energy consumption for existing envelop insulation values (Wall Insulation R= 6 and Roof Insulation R=6) was simulated and compared with energy consumption of proposed insulation (wall insulation R=9 and roof insulation R=9) which achieved a further reduction of 1.93% compared to the existing insulation level which emphasized the need for retrofitting and replacing the wall and roof insulation. One very important observation writes the stronger impact of color yielding 2 % decrease in annual energy consumption compared to the darker color, an option that carries minimal cost and would be an economically attractive option for retrofits and new designs.

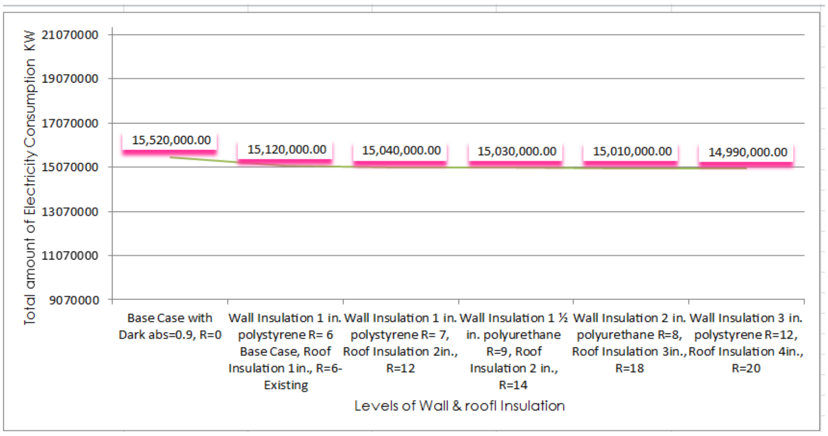

Figure 6: *Simulation results applying façade insulation for Latifa Hospital, Dubai using 2013 weather data.*

Comparing the existing façade colour for retrofitting (wall abs=0.6 and roof abs.=0.4) to the proposed façade colour (wall abs.=0.4 and roof abs.=0.4) yields a reduction of 0.1% in annual energy consumption which indicates that the current façade colour is optimized and offers least opportunities for further energy savings.

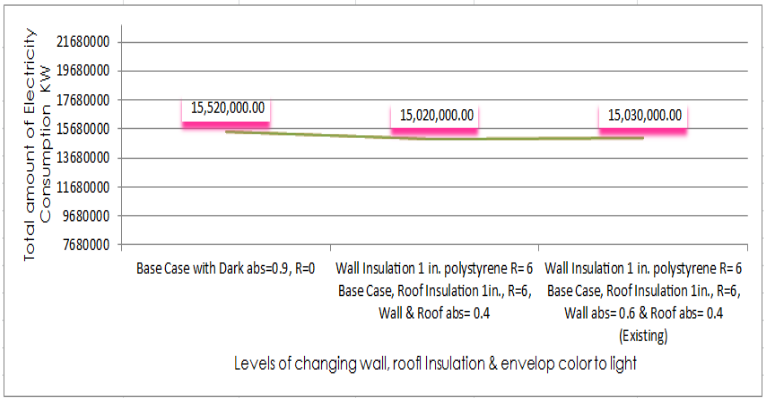

Figure 7: *Simulation results investigating façade colour for Latifa Hospital, Dubai using 2013 weather data.*

Window Optimization

Proper placement of windows and optimized window to wall ratio achieves have a strong impact on energy consumption in the climatic context (Fathy, 1986). In order to optimize window to wall ratio

(WWR), it was increased from a minimal of 10 % to relatively higher value of 45 % and a discrete energy performacne trend was observed in three differenct WWR regimes. In the first regime, increasing WWR from 10.5 to 20 % has negligible increase in energy consumption primarily because the increase in heat gain is compensated by the decrease in area lighting load of the indoors. In the second regime increasing WWR from 20% -30% increased the energy consumption modestly which shows that the benefit of increased ligitng loads are being outclassed by the increase in heat gain. In the third regime, increasing WWR beyond 30 % yielded a sharp increase in energy consumption which indicated that at this stage only heat gain is the consequencial for the increasd WWR which emphasizes economic implications of increasd WWR beyond a certain range. The simulated results agree with similar research which recommends WWR of 10-20% for better energy performance [Aboulnaga, 2006]. Comparing the optimum range of WWR of 20-30 % computed through simulations with the existing building WWR of 17 %, it is proposed that for retrofitting the glazings should be increasd up to 25 % to have better daylight for a healthier indoor climate critical for hospital buildings even at the cost of affordable extra energy consumption.. At the second stage different window types were simulated and it was observed that replacing the existing double clear/ tint glass type to double low-e a reduction of 0.7 % in energy can be achieved which shows that while retrofitting, the window type needs to be re-considered..

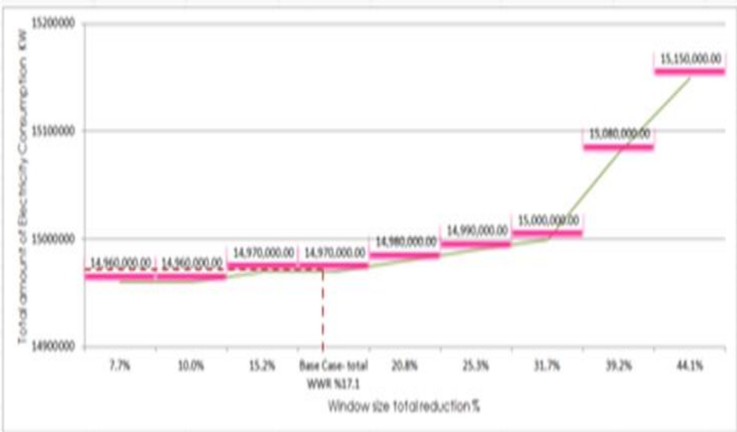

Figure 8: *Simulation results with various WWR for Latifa Hospital, Dubai using 2013 weather data.*

Optimizing HVAC

Energy Efficiency Ratios (EER) of the HVAC was studied against energy consumption in the ange of EER =10 to EER= 26 shown in figure 9.

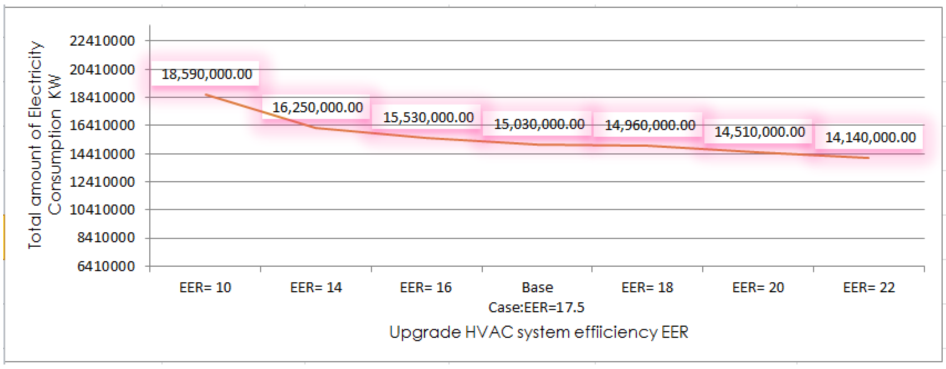

Figure 9: *Simulation results for cooling system energy efficiency for Latifa Hospital, Dubai using 2013 weather data.*

The existing EER of the system being 17.5 was compared with a higher EER value of upto 26 and it is observed that energy consumption can be reduced by 5.92% while increasing the EER to 22. It is therefor emphasized that selecting a higher efficiency cooling system can save a huge amount of energy and the cooling system should be replaced with more efficient system while retrofitting.

Optimizing Comfort Conditions

A general observation made in UAE is a trend of setting thermostate to undesirably (and at times uncomfortably) low temperatures around 20-22 °C which has its implications on energy consumption and oprations cost. Effective and comfortable cooling can still be achieved keeping the thermostat set point at a higher temperature and increasing a little more fan ventilation. An attempt was made to simulate the trend of the impact while changing the thermostate set-point from 22 °C to 24 °C in occupied areas and from 26 °C to 28°C in unoccupied areas being still in the comfort zone based on psychometrics of the place. The result shows a reduction of 0.27% in annual energy consumption which emphasized the importance of operating the cooling system at right comfort conditions without sacrificing comfort.

Optimizing Fan Type

Installing Variable Frequency Drives (VFDs) on the supply and return fans of the Air Handling Unit (AHU) can reduce energy consumption by 20% (Schneider Electric, 2006). In order to test this, the existing constant-volume air handling system with centrifugal fan type was replaced VFDs on the supply and return ducts of the AHUs. The results show a reduction of 20.23% in the annual energy consumption. Although the simulation result showed a substantial potential reduction in energy consumption, this type of fans cannot be used in the hospital environment as the variable VFD causes ventilation problem in low cooling load conditions and causes associated health hazard. It is therefore proposed to keep the same fan type.

Integration of Solar Thermal Collectors

The hospital has a 12,000 lit/day hot water consumption which demands a large amount of energy for water heating. Since UAE has vast solar energy potential, heating problem was solved by integrating solar thermal collector on the roof to provide hot water. The system consists of 18 collecotrs with aperture area of 1.87 m^2, water mass flow rate of 35 kg/hr and water tank capacity of 300 lit each. It is coupled with an auxiliary electrical heating system to constantly supply hot water at 63 °C.

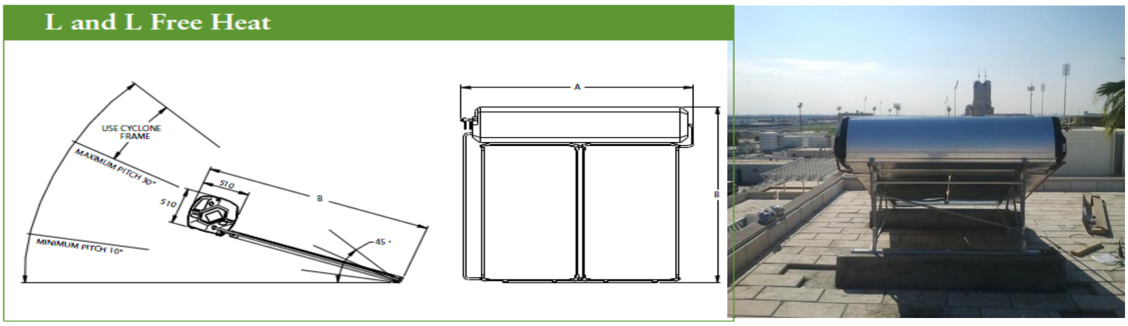

Figure 10 *Solar Thermal Collector installed on the roof of Latifa Hospital, Dubai.*

In order to determine its performance, the solar thermal system is simulated in TRNSYS softwate using

Dubai weather data to find out the ratio of solar thermal energy supplied to the auxiliary energy needed for the stable 63 °C supplywater temperature. The solar thermal system attained a total yearly thermal energy production of 212,224 KWh which contributed 46 % of the total energy consumption for hot water production in the hospital and therefore it is recommended that the share of solar thermal should further be increased to attain energy efficient and cost competitive hot water production.

CONCLUSION

This paper has explored energy saving opportunities while retrofitting an existing healthcare facility in Dubai, UAE through a simulation scheme. The simulations findings resulted in a number of recommendations for energy efficient and cost competitive retrofitting solutions in the climatic context while pointing out indicative impact of occupants' behavior on energy consumption of cooling system.

The findings are in three different areas. First, for the façade construction, choosing a lighter color has huge impact reaching up to 2 % energy savings with least cost incurred, adding wall and roof insulation yields up to 3.4 % energy savings although they incur additional cost as well, proper window type can yield up to 0.7 % of energy savings with minimal cost addition and the optimum WWR is a found between 20-25 % for healthier indoors with little extra energy cost. Secondly for HVAC system operation and efficiency, keeping the cooling set points within acceptable comfort can achieve 0.27 % energy savings with no extra cost and replacing the existing HVAC with a more efficient cooling system can achieve up to 5.9 % energy savings with extra cost of system. Finally integration of 18 solar thermal collectors in the building as a means of renewable and environmental friendly source of energy contributed to 46% energy saving for hot water production economically competitive rates and therefore is recommended for a higher energy share.

ABSTRACT

The construction sector and the associated built environment have an oversized footprint. They are responsible for more than a third of global resource consumption and an estimated 40% of the total waste generation, contribute up to 30% of global annual greenhouse gas emissions and consume a third of all energy. The retention, rehabilitation and reuse of the existing building stock play a pivotal role in the sustainable development of the city. However, there is an ongoing debate on evidencing the sustainability of refurbishment in contrast to demolition and new construction. On the one hand, a newly constructed building can achieve higher operating energy efficiency on the short term, on the other hand, when looking at lifespan, material use and waste generation, re-use or continued use of the buildings is more environmentally sustainable than to demolish and replace them. This paper provides a review of the role of sustainability in the built environment and reflects on this from the perspective of refurbishment; revealing the state of the art regarding the definitions of sustainability, the sustainability legislation on different scale levels and the assessment methods used to certify sustainable buildings. Subsequently, these different aspects will be put in relation to each other and assessed from the perspective of refurbishment.

INTRODUCTION

The construction sector and the associated built environment consume significant quantities of resources and energy, contribute to climate change, and affect the health and well-being of building users and others (Todd, 2012). In 2011 the United Nations Environment Program (UNEP) and the Sustainable Buildings and Climate Initiative (SBCI) released a report (United Nations Environment Programme, 2011) that notes:

1. The built environment is the single largest contributor to global greenhouse gas emissions (GHG), with approximately one third of global energy end use taking place in the operational use of buildings.
2. The construction sector is responsible for more than a third of global resource consumption, including 12% of all fresh water use, and contributes 40% of the generation of solid waste.
3. Constructing new green buildings and retrofitting existing energy- and resource- intensive

L.C. Havinga MSc. is a doctoral candidate in the Department of the Built Environment, Eindhoven University of Technology , the Netherlands. Prof. dr. B.J.F. Colenbrander is a full professor at the chair of Architecture, History and Theory in the Department of the Built Environment, Eindhoven University of Technology. Dr. ir. H.L. Schellen is an associated professor at the chair of Building Physics in the Departmennt of the Built Environment, Eindhoven University of Technology.

buildings stock can achieve savings of about one-third in energy consumption in buildings worldwide and significantly contribute in the reduction of CO_2 emissions.

4. Greening buildings will bring significant health and productivity benefits.

It is made clear that interventions are not only necessary, but possible. According to Petersdorff et al (Petersdorff, Boermans, & Harnisch, 2006), the main energy and CO_2 saving potential lies in the existing building stock. Most developed countries have regulations consisting of national performance standards for newly built houses. The demolition rate in the building stock can be estimated to be ~½–1%, whereas new constructions to be 1% of the total living area per year, thus resulting in a slight increase of the existing building stock (Petersdorff e.a., 2006). Research in the UK (Power, 2008) suggests that even with ambitious new building programs and a high demolition rate, only 10% of the current stock will have been demolished by 2050, arguing the urgent need to upgrade the existing stock on the grounds that 70% of all homes that will exist in 2050 are already built. Consequently, existing buildings must be sustainably refurbished (Häkkinen, 2007),(Sev, 2011), minimizing the operational energy use while taking into account other sustainability aspects. This paper provides a review of the role of sustainability in the built environment and reflects on this from the perspective of refurbishment. Revealing the state of the art regarding the definitions of sustainability, the sustainability legislation on different scale levels and the assessment methods used to certify sustainable buildings. Subsequently these different aspects will be put in relation to each other and assessed from the perspective of refurbishment.

DEFINITION

In today's world, the term sustainable development is everywhere; over 500 definitions of sustainability and sustainable development have been spawned by various governments, professional bodies, institutions and organizations (Shah, 2012). The growth of sustainable awareness dates back many decades; from Silent Spring written by Rachel Carson (Carson, 2002) and first published in 1962, describing a world affected by pesticides and chemicals, through to James Lovelock's Gaia (Lovelock, 2000), first published in 1969, stating the role of 'mother earth'. One of the first definitions of sustainable development was made in 'Our common future', the report of the Brundtland Commission, calling for development "that meets the needs of the present without compromising the ability of future generations to meet their own needs"(World Commission on Environment and Development, 1987). Whilst this definition is still used today, a more commonly known terminology encompasses the environmental, social and economic principles captured as the 'triple bottom line' (Elkington, 1998), also referred to as the three P's; Planet, People, Profit.

The definitions of the terms 'sustainable building' and 'building sustainability performance' vary according to different actors of the construction industry. The internationally standard definition of a green building is provided by ASTM Standard E2114–04 (E06 Committee, 2004), that is, "a building that provides the specified building performance requirements while minimizing disturbance to and improving the functioning of local, regional, and global ecosystems both during and after its construction and specified service life". Furthermore, "a green building optimizes efficiencies in resource management and operational performance and minimizes risks, which threaten the human health and environment". By emphasizing performance requirements and human health, the principles of the triple bottom line are integrated within this definition of a green building. Also, it specifically mentions the importance of taking into account the different stages of a buildings lifespan, from construction and service lifespan, to what happens after a buildings service lifespan.

LEGISLATION

Worldwide Legislation

The United Nations Framework Convention on Climate Change (UNFCCC) was negotiated at "the

Earth Summit", the United Nations Conference on Environment and Development (UNCED) held in Rio de Janeiro in 1992. The objective of this international environmental treaty is to "stabilize greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system". The Kyoto Protocol is an international agreement linked to the UNFCCC, which commits its Parties by setting internationally binding emission reduction targets. The main goal of the Kyoto Protocol is to contain emissions of the main anthropogenic (i.e., human-emitted) greenhouse gases (GHGs) in ways that reflect underlying national differences in GHG emissions, wealth, and capacity to make the reductions. The first round of the protocol was completed in 2012, but much greater emission reductions will be required in future to stabilize atmospheric GHG concentrations (Oberthür & Ott, 1999).

European Legislation

For meeting the commitments on climate change made under the Kyoto protocol, the EU has introduced legislation to ensure that buildings will consume less energy in the future. A key part of this legislation is the Energy Performance of Buildings Directives (EPBD). The first directive (Directive 2002/91/EC,EPBD), first published in 2002, requires that an energy performance certificate (EPC) is made available when buildings are constructed, sold or rented out. The certificate has to express the operational energy performance of the building. Also, every country had to insert legislation stating a minimum performance. Subsequently, the second Directive (Directive 2010/31/EU, EPBD) states, that "Measures are needed to increase the number of buildings which not only fulfil current minimum energy performance requirements, but are also more energy efficient, thereby reducing both operational energy consumption and carbon dioxide emissions. For this purpose Member States should draw up national plans for increasing the number of nearly zero-energy buildings and regularly report such plans to the Commission". Also, being more specific, Article 9 states: "Member States shall ensure that: by 31 December 2020, all new buildings are nearly zero-energy buildings; and after 31 December 2018, new buildings occupied and owned by public authorities are nearly zero-energy buildings".

There are only very limited mandatory requirements related to building components and materials used in buildings, in practice energy-saving measures predominate. The mandatory requirements that currently exist in the EU countries studied by Reijnders & Van Roekel (Reijnders & van Roekel, 1999) deal only with very limited aspects of the interactions between buildings and the environment.

ASSESSMENT METHODS

As mentioned, an Energy Performance Certificate is obligated in Europe when a building is constructed, sold or rented out, therefore this type of certificate will be considered first. Subsequently, a wider range of building environmental assessment (BEA) tools, which are all voluntary and motivational in their application, will be considered. The field of BEA has matured remarkably since the introduction of the UK Building Research Establishment Environmental Assessment Method (BREEAM) in 1990, and the interim period witnessed a rapid increase in the number of tools (Cole, 2005). Reijnders and van Roekel (Reijnders & van Roekel, 1999) have made a rough division of BEA tools into two groups. The first group includes those, which are based on scores and a criteria system and are regarded as qualitative tools, the Criteria Based Tools (CBT). The second group includes the tools that use life cycle assessment (LCA) methodology with quantitative input and output data on flows of material and energy throughout the different stages of a buildings life cycle, from construction and use to demolition and recycling. For each category, the EPC, CBT and LCA, firstly the sustainability criteria and methodology will be introduced, secondly the pros and cons of their application will be elaborated, and thirdly they will be assessed from the perspective of refurbishment.

Energy Performance Certificate

Criteria & Method. The definition of the energy performance of a building is the amount of energy, actually consumed or estimated, necessary to meet the performance requirements associated with a standardized operational use of the building (Poel, van Cruchten, & Balaras, 2007). The criteria that are used in these calculations are: insulation values, technical and installation characteristics (including own-energy generation), design and positioning in relation to climatic aspects, solar exposure (taking into account the influence of neighbouring structures), and indoor climate factors that influence the energy demand. The Energy Performance Certificate is a document that indicates the operational energy performance of a building as a numerical output, calculated according to a methodology based on the general framework set out by the EPBD. Following the first EU directive, all EU countries have stated a minimum performance. There are many different software programs that allow these calculations to be made, most programs use an interactive model where the user can easily adjust for example the R-value (thermal resistance) of a wall, the type of ventilation system used or whether there are solar panels on the roof or not. These changes immediately result in a change in the Energy Performance, allowing for the user to compare the effect that different options have on the energy use of the building.

Pros & Cons. An EPC is based on the quantitative calculation of the operational energy consumption, creating an objective basis to assess and compare design solutions and buildings. These programs are relatively easy to use and allow for the user to integrate the outcomes at an early stage of the design process. Also, a study by Ronan Lyons (2013) has shown a positive impact of the Energy Performance Certificate on sales and rental prices of buildings on average in most of the Member States that were analysed, indicating that better energy efficiency is rewarded in the market. On the down side an EPC only covers the operational energy use of a building, disregarding not only the stages of construction, maintenance and eventual demolition and recycling, but also the resources that are being used and the environmental impacts that are related with them.

Refurbishment. Energy Performance Certificates are also applicable to existing dwellings and refurbishment projects. Although, since an EPC focusses on operational energy use and doesn't take into account sustainability factors like resource use and waste production, it could be considered easier to attain the best EPC rating th rough demolition and new construction rather than through refurbishment of an existing building.

Criteria Based Tools.

Criteria & Method. The Criteria Based Tools essentially consist of lists of suggestions for the environmental improvement of buildings linked with a score (Reijnders & van Roekel, 1999). Among the criteria-based tools (CBT) are Building Research Establishment's Environmental Assessment Method (BREEAM) and Civil Engineering Environmental Quality Assessment and Award System (CEEQUAL) (UK), SBTool (International), Leadership in Energy and Environmental Design (LEED) (USA), High Environmental Quality certification (HQE) (France), EcoProfile (Norway), PromisE (Finland), Green Mark for Buildings (Singapore), H K-BEAM and CEPAS (Hong Kong), Green Star (Australia). BREEAM is the leading and most widely used criteria based environmental assessment method for buildings (Nguyen & Altan, 2011). It was developed in the UK in 1990 and is the building environmental assessment method with the longest track record. The CBT's cover a wide range of criteria which are classified into categories (e.g. BREEAM): Energy, Transport, Water, Waste, Materials, Land Use & Ecology, Health and Wellbeing, Pollution, Management, Innovation. The method of a CBT typically consists of three major components (Cole, 2003).

1. Structure; a declared set of environmental performance criteria organized in categories.
2. Scoring; the assignment of a number of possible points or credits for each performance issue that can be earned by meeting a given level of performance.
3. Output; a means of showing the overall score of the environmental performance of a building or facility, usually involving a weighting system that is assigned to the different categories.

Pros & Cons. The Criteria Based Tools offer a wide range of sustainability aspects; there are even credits to be earned considering whether there is a bus stop nearby or not. On the downside, the coverage is rather superficial (Reijnders & van Roekel, 1999) and is not based on a systematic study of environmental impact related to the factors concerned; it is unclear whether the effects of the environmental improvements suggested are marginal, substantial or large (Reijnders & van Roekel, 1999). Additionally, weighting is inherent to the systems and when not explicitly, all criteria are given equal weights (Todd et al., 2001). According to Lee et al. (2002) weighting is the heart of all assessment schemes since it will dominate the overall performance score of the building being assessed. However, there is still no consensus on the assignment of weightings. The Green Building Challenge aims to provide a default weighting system, taking into account regional differences by encouraging users to change the weights. However, although sustainability issues differ from region to region, there is no consensus on regional weighting systems. There is a concern that it is possible to manipulate the results, if the default weighting system is altered in order to satisfy specific purposes (Larsson, 1999;Todd et al., 2001)(Ding, 2008).

The Criteria Based Tools are very complex, it requires training and certification to be able to use them (Nguyen & Altan, 2011). As a result, they are not accessible and are often used as a checklist at the end of the design stage instead of being used early in the design process while the most important decisions with regard to sustainability should be made at the beginning of the design process (Zeiler, 2011). Environmental issues are broad and difficult to capture, combining qualitative and quantitative data, a balance between completeness of coverage and ease of use remains one of the challenges in developing an environmental building assessment tool (Ding, 2008).

Lastly, developers and designers use the CBT's to attain an overall desired "score": a BREEAM "Excellent" or "Very Good," or LEED "Gold" or "Silver". The goal of achieving a high score may be considered to be more important than achieving a good overall product (Cole, 2003). In addition, the results of all categories are converted into a score. Each category has to attain at least a "pass", however, categories have very limited or no minimum requirements and a detraction of credits for polluting components does not exist. Therefore, a project can contain very environmentally unfriendly components in a specific category, and still achieve a high final score. This checklist approach, where the meeting of individual performance requirements is pursued in the quest for a certain overall rating, detracts the designer from the more fundamental issue of ethics and professional responsibilities. More skilled design teams recognize that the interrelationship between the different strategies and systems is key to successful sustainable design (Cole, 2003).

Refurbishment. Some CBT's (e.g. BREEAM) have developed a special tool for refurbishment, in which the criteria and weightings are adapted to suit refurbishment better. Refurbishment can thus be tested by means of these tools, however, cannot be compared to new construction, because it concerns separate tools whose scores are not comparable.

Life Cycle Assessment Tools.

Life Cycle Assessment (LCA) is "a method for analysing the environmental burden of products (goods and services) from cradle to grave, including extraction of raw materials, production of materials, product parts and products, and discarding them by recycling, reuse, or final disposal" (Guinée, 2002). LCA is defined as "the compilation and evaluation of the inputs, outputs and potential environmental impacts of a product system throughout its life cycle" (International Organization for Standardization (ISO), 1997). The most advanced and most used software tools for Life Cycle Assessment of products are Simapro (Netherlands) and Gabi (Germany). Life Cycle Assessment software tools that can be used to assess buildings include: ECOSOFT (Austria), EcoCalculator (Canada), Eco-bat (Switzerland), LEGEP (Germany), GaBi-Build-IT (Germany), SBS (Germany), ELODIE (France) EQUER (France) COCON (France), ECO-QUANTUM (The Netherlands), GreenCalc+ (The Netherlands), EcoEffect (Sweden), IMPACT (UK) and BEES (USA).

The indicator called "embodied energy", lies at the basis of Life Cycle Assessment. The so called "initial" embodied energy is the sum of the energy that is consumed by all of the processes associated with the production of a building, considered as if that energy was 'embodied' in the product itself. As buildings are designed to be more and more energy efficient during the operational phase of the life cycle, the initial embodied energy becomes relatively more significant. The initial embodied energy of a building is a significant multiple of the annual operating energy consumed, ranging from around 10 for typical dwellings to over 30 for office buildings (Ciravoğlu & Taygun, 2013).

The "gross life cycle embodied energy" consists of the total embodied energy during the life cycle of a building, taking into account not only the initial embodied energy that was used in initially construct the building, but also the operational energy, the embodied energy used during maintenance and/or refurbishment and the energy used to dismantle or demolish the building and dispose of- or recycle the materials (Ciravoğlu & Taygun, 2013). With the recycling and re-use of the materials, a part of the embodied energy of those materials can be detracted from the gross life cycle embodied energy. Based on LCA, a zero energy building consists of a building which will produce enough energy during its lifetime to recover this energy debt (Storey and Baird, 1999), while a zero energy building generally only accounts for the energy debt created during the operational use of the building.

The aspect of embodied energy, although it is vital to the ideology of Life Cycle Assessment, is only part of the actual assessment methodology. Following ISO 14040, an LCA consists of four components or steps (AIA Guide to Building Life Cycle Assessment in Practice);

1. Goal and Scope Definition,
2. Inventory Analysis,
3. Impact Assessment,
4. Interpretation.

In addition to the calculation of embodied energy, which is part of the inventory analysis, environmental effects and impacts are also assessed in LCA methods. These consist of (e.g. EcoQuantum v.2.00): Environmental effects; Material use, Energy consumption, Water consumption. Environmental Impacts; Depletion of abiotic resources potential (ADP) Global warming potential (GWP), Ozone depletion potential (ODP), Photo-oxidant formation potential (POCP), Human toxicity potential (HTP), Aquatic ecotoxicity potential (AETP), Sediment ecotoxicity potential (SETP), Terrestrial ecotoxicity potential (TETP), Acidification potential (AP), Eutrophication potential (EP)(Itard & Klunder, 2007).

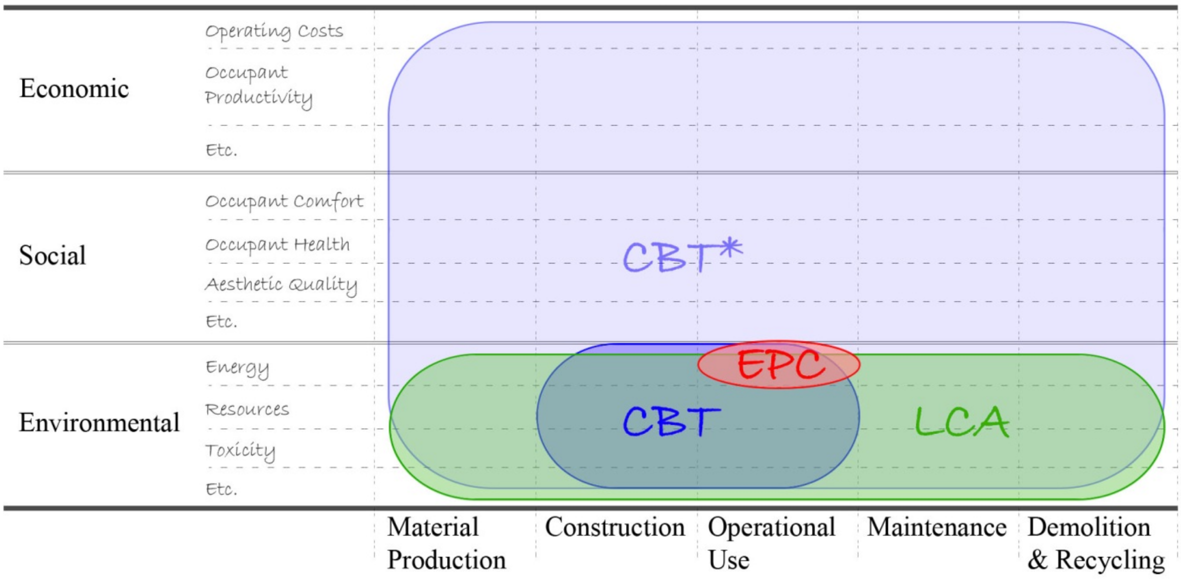
Pros & Cons. LCA is a scientific way of determining environmental impacts, based on international databases, calculation methods and ISO standards. The LCA-based methods have an in-depth coverage of environmental impacts associated with design and building materials. The latter is not unexpected because the methodology essentially builds on LCAs of products used in the building industry. Moreover, LCA-based instruments allow for estimates of the relative improvements associated with specified changes in design or the choice of building materials (Reijnders & van Roekel, 1999). LCA is based on a long-term vision, taking into account not only what is sustainable now, but also relating this to the past and the future of a product. Doing an LCA for buildings is very complex (compared to normal 'products') for four reasons; firstly buildings have a long and difficult to predict longevity, secondly a building usually undergoes many changes in form and / or function during its lifetime, thirdly a significant part of the environmental impact takes place during its use, fourthly, every building is unique and there are many different parties involved in the life cycle of a building. For these reasons, and because LCA is relatively new to the building industry (AIA Guide to Building Life Cycle Assessment in Practice), they are still less developed and less widely used than the CBT methods. Also, LCA contains no direct coverage of the indoor environment (Reijnders & van Roekel, 1999).

Refurbishment. LCA is ideal for evaluating a refurbishment process compared to other options. When taking into account the existing embodied energy already present in the existing building and the energy and materials used during demolition and construction of a new building, it is possible to compare the environmental impacts of refurbishment versus demolition and new construction through LCA.

CONCLUSION AND DISCUSSION

When the definition of sustainability, the existing legislation in the field of sustainability and the existing certificates and methods in the field of sustainability are put into relation with one another it becomes clear that these don’t match. The legislation, and the consequent Energy Performance Certificate, concentrates on energy consumption during the operational use of a building. The commonly accepted definition of sustainability, the triple bottom line, focuses on environmental, social and economic health; planet, people, profit. These three categories are also reflected in the standard definition of a “green building”, in addition, it specifically mentions the importance of taking into account the different stages of a buildings life, from construction and service life, to what happens after a buildings service life. The latter lies at the basis of Life Cycle Assessment methods: covering a much wider spectrum of environmental sustainability, taking into account different stages of the buildings life cycle and concerning a large range of environmental impact criteria in addition to energy. Social and Economic aspects, however, are not reflected in an LCA. The Criteria Based Tools do take into account economic, social and environmental sustainability aspects, although the main focus lies on the environmental sustainability impacts during the construction and operational use stages. These different areas of sustainability **are shown in Table 1**, clearly showing the extremely narrow part of sustainability that the legislation and the associated Energy Performance Certificates are focusing on. Also, the Criteria Based Tools have two separate indicated areas, one that stands for its main focus area, and one covering the wide range of rather superficial indicators covering the entire spectrum of sustainability.

Table 1. Spectrum of Sustainability in the Built Environment



The fact that legislation and regulations are concentrating on energy consumption during the operational use of a building has led to this principle being translated as “sustainable” in practice. A building is considered to be extremely sustainable when a zero energy value is achieved. The fact that in these cases other aspects of sustainability are completely ignored is problematic. Concepts such as "passive building" and "energy-neutral home" are popular, and national and international standards concentrate on attaining extremely high insulation values of the shells of buildings. That this insulation may often be environmentally polluting is completely disregarded. Also, there is for example the extensive use of solar panels to balance out the operational energy, while completely disregarding the embodied energy and environmental impact that was necessary to create the solar panels in the first place, a kind of deceptive sustainability. In relation to refurbishment, these regulations are also very problematic. Buildings that reach a certain age fall short of adequate operational energy efficiency to fill current standards, and are consequently threatened by large-scale demolition; to achieve the highest possible energy label demolition and new construction often are an easier option than refurbishment. The embodied energy present in these buildings will be discarded, the resources used in the new construction will not be accounted for, and the waste that is produced because of this is ignored. These things will not stand in the way of the newly constructed building achieving the highest energy certificate level, nor will it stand in the way of the newly constructed building being awarded sustainability prices and being promoted as “best practice”.

However, as described in the article, there are other assessment methods that try to provide a more complete assessment of sustainability. Unfortunately, they are very complex and require training and certification to be able to use them (Nguyen & Altan, 2011). As a result, they are not accessible and are often used at the end of the design stage instead of being used early in the design process while the most important decisions with regard to sustainability should be made at the beginning of the design process (Zeiler, 2011). They are therefore, and because they are completely voluntary in their application, far from standard in use.

The use of a different list of indicators in different approaches makes a definition of the term “Sustainable Construction” subjective and causes difficulties in comparing results from different tools. A case-study comparison by Zeiler (Zeiler, 2011) where eight different case studies were tested by four of the most popular assessment methods (LEED, BREEAM, Greencalc, Ecological Footprint), proved the outcomes to be completely different. A building could be considered most sustainable by one tool, and least sustainable by another. In order to overcome these constraints, both the International Organization for Standardization (ISO) and the European Committee for Standardization (CEN) have worked actively in the last few years to define standard requirements for the environmental and sustainability assessments of buildings (Mateus & Bragança, 2011). Both standards ISO/TC59 and CEN/TC350 take into account economic, social and environmental sustainability and aspects regarding a products life cycle from cradle to grave, they provide general definitions and principles regarding indicators and calculation methods for assessment tools. These standards do not set the rules for how building assessment schemes may provide valuation methods, nor does it prescribe levels, classes or benchmarks of performance (Technical Committee CEN/TC 350, 2010). Since these standards are not mandatory nor completed yet (especially on the part of social and economic sustainability), they haven’t been fully integrated in the assessment tools yet.

Efforts are being made to integrate LCA methodologies in CBT tools, trying to combine the measurability of LCA’s with the wide range of sustainability aspects covered in a CBT. Environmental issues are broad and difficult to capture, combining qualitative and quantitative data, a balance between completeness of coverage and ease of use remains one of the challenges in developing an environmental building assessment tool.

Sustainable Hotel Industry from the Perspective of the Social Environmental Management

Alexander González Castaño, M.Arch PhD
[Universidad Pontificia Bolivariana de Medellín
LEET – Laboratorio de Estudios y Experimentación Técnica en Arquitectura]

Esteban Pineda
[Terra BioHotel]

ABSTRACT

Sustainable projects development cannot be considered just from the perspective of passive design, sustainable construction, and energetic efficiency of the building during its life cycle. Other dimensions of systemic sustainability must be involved as a part of the real-estate management model, in order to increase its importance and establish equity and efficiency based on relationships with the economic and cultural context where each project is located. This point of view starts off by recognizing that construction is not just a contaminating, noisy and negative transformer of the physical medium activity, but it is also a promoter of positive cultural and social transformation of the community located around the project.

A social-environmental management model is presented based on this condition, which allows a hotel-oriented construction to establish cooperation and integration networks with its neighbors, starting right from the preliminary design stage, the construction stage and involving its future operation. This sustainable social management model involves, during the development of the Terra Bio-hotel project, the participation of social sciences professionals like historians, sociologists and anthropologists, whose management of the community made possible to include the hotel project, during its construction process, in the imaginary of a traditional community of Medellin, embracing a contemporary project as a new neighbor, which stimulates the life in the neighborhood and joins the community with cultural, artistic and environmental management activities. In this social-environmental management stands out the participation of the neighborhood administration board on the projection of its social model with a regional scope, through projects like: agro-ecological market, solid waste comprehensive management and historical memory recovery.

INTRODUCTION

In terms of population and economic dynamism, Medellin is the second largest economy in Colombia and holds a high visibility within the Latin-American region, due to its recent development in urban infrastructure and equipment. It has been a decade since the city was projected as a business destination by promoting and consolidating it internationally. However, its hotel infrastructure –which is expected to host a high volume of visitors and people invited to different fairs, conferences and events- does not differ significantly from a traditional model of hotel industry that makes an intensive use of renewable and non-renewable resources, such as water, energy and food – involving high environmental and social impacts during the life cycle of buildings. In this scenario, alternative experiences serving as a model –or laboratory- are pertinent and useful in order to incorporate the notion of systemic sustainability in Colombia's and Latin America's hotel industry.

Terra Biohotel is a hotel project with 41 rooms and an area of 2,666 m^2 built (about 28,697 ft2). From its design phase, it was conceived as a technical and technological innovation proposal based under the principles of "Systemic Sustainability" (El Khouli, 2011), "Territorial Social Responsibility" (in Spanish "Responsabilidad Social Territorial") (Alquimia, 2012) and "Glocalization" (Robertson, 2003). These conceptual premises aim to minimize the negative social-environmental impacts and to potentiate the positive impacts of the hotel project throughout its life cycle. In order to carry this out, sustainable strategies were implemented in Terra Biohotel during its design and construction phases, while actions to guide the project sustainability during its operation phase are planned.

SUSTAINABILITY IMPLEMENTED IN THE DESIGN PHASE

Bioclimatic passive design strategies in Terra Biohotel architectonic project are based on the analysis of the location, the environmental preexistences and the variables prioritization such as solar incidence, natural lighting, natural ventilation and noise (García, González, & Salazar, 2006), and were complemented with the method of projecting for the High Environmental Performance Architecture (AADA, for its acronym in Spanish) (Bedoya, 2011) The results of this design exercise made it possible to build a structure whose exposure to direct solar radiation is minimized (See Figure 1, letter a). The project counts on a performance of natural lighting superior to 8 hours a day and a natural ventilation system that allows guests to do a secondary use of the air conditioning system, achieving –this way- energy efficiencies superior to 50%, compared with a conventional building of the hotel industry in Medellin.

SUSTAINABILITY IMPLEMENTED IN THE CONSTRUCTION PHASE

Social-environmental resident building manager: according to the current building policy in Colombia, it is not mandatory to hire this type of professionals in private projects. However, Terra Biohotel decided to employ an environmental engineer, so he could control the environmental impact during the construction phase, as well as the social relationships between the neighborhood residents and the Project.

Construction and Demolition Debris (C&DD) comprehensive management: during the construction phase of the project, C&DD were constantly separated at source (See Figure 1, letter b), which maximized their subsequent reusing and recycling. The results obtained from these processes are: 514 m3 (about 18,152 ft3) of C&DD were reused in a road in a near construction site; 449 m3 (about 15,856 ft3) of concrete, mortar and stone material waste were recycled and concrete blocks for the hotel envelope construction were made with it; 6,900 kg (about 15,211 lb) of wood were reused as biomass; 593 kg (about 1,307 lb) of metallic waste and 188 kg (about 414 lb) of polyvinyl chloride (PVC) were recycled by specialized companies. In the course of the construction process, paper, cardboard, glass and plastic were constantly separated and given to an informal recycler who worked in the neighborhood.

Figure 1 (a) Sample of sun protection element in the building and (b) C&DD separation.

Water resources comprehensive management: Throughout the construction phase, a water recirculation system was installed in the block cutter machine and in the concrete mixer. Water losses produced during the cut were supplied with the water resulting from the concrete mixer washing, producing –as a result- a closed cycle for water reusing (See Figure 2, lettes a and b). Such strategy made it possible to reuse 34,413 l (about 9,090 US gal) of water which contained a high amount of sediment, and to prevent their discharging as well as the contamination of proximate water sources and possible obstructions in the urban rainwater harvesting systems.

Selection of materials: the materials selected for the construction phase of the project were eco-materials, coming –as much as possible- from low-polluting production processes and from recycled materials that could be recycled again at the end of their life cycle. Moreover, in order to prevent a high level of emissions to the atmosphere due to the transportation, materials were locally obtained. The most representative material in the project is the recycled concrete block which was used in the masonry of the building. This material is made up of a 38% of recycled concrete and the block supplier company has been provided with it– as a by-product of the construction phase- by Terra Biohotel. The 95,237 blocks required for the construction phase contain 268 metric tons of recycled concrete, which is equivalent to the same amount (in metric tons) of natural stone aggregates that did not have to be exploited in the quarries of the area.

During the execution of the structural concrete, Fuel Oil N. 2 was replaced by a natural oil coming from the castor oil plant and used as a non-stick and mold release agent for the concrete formworks, avoiding –this way- the generation of a dangerous waste with a high potential of water and soil polluting.

Atmospheric emissions and noise control: the measures implemented to mitigate the spread of particulate matter in air and to reduce the sound pressure levels which the residents living near the project are exposed to were: 1) Covering the fine construction materials and the excess material from excavations. 2) Moistening uncompleted surfaces as well as those ready to be swept. 3) Closing the area intended for the block cutter and concrete mixer since they were potential sources of noise. With the objective of improving the acoustic insulation of these closing areas, part of the expanded polystyrene used in other construction processes was reused. Introducing such measure for reducing air and noise pollutants contributed to the cordial relationships with the people living near the construction, who recognize that *Terra Biohotel* is a social caring company.

Construction worker training: the project construction workers were constantly trained about sustainability and safety, which contributed to create an environmental awareness and a self-protection consciousness (See Figure 2, letter c). These experiences were later replicated in other construction projects. They also implemented some of the new ideas, such as management and care of water, in their own homes.

Figure 2 (a) Double sedimentation in the process of block cutting, (b) Pumping of clarified water to be reused later in the block cutter and (c) Construction worker training.

Sustainable School-Hotel: during the construction process, the transference of experiences and knowledge was fostered. Terra Biohotel has embraced students and professors from different universities of Colombia who have been interested in going into detail about the sustainable component of the project (See Figure 3, letter a). Some of the undergraduate students are carrying out scientific initiation researches, graduation theses and professional practices about the project development. The initiative of "Sustainable School-Hotel" aims to transmit a message of systemic sustainability to the community, to the government and to the organized civil society, by means of the promotion of networking and mutual learning and citizen awareness about the clear connection between their consumption habits and life style with the environmental degradation and the magnification of the social gap separating individuals in a same community.

Development of a sustainable community: with the goal of putting into practice the systemic sustainability approach, set as one of the most important premises in the project *Terra Bio Hotel*, it was necessary that the management model went beyond the notions of passive design, energy efficiency and construction under environmental sustainability, towards the development of a sustainable community. To carry this out, *Terra Biohotel* unified efforts and works with the Communal Action Board of the neighborhood *Los Conquistadores* in the city of Medellin, whose leaders and representatives agreed with the objectives to develop sustainable management initiatives in the area of the hotel project. It is also expected that the residents take responsibility –individually and collectively- for their negative social-environmental impacts and take part in the execution of specific tasks, namely the mitigation or reversion of such impacts.

This social collective work, together with the Communal Action Board of the neighborhood *Los Conquistadores*, favored the spreading of the sustainable systemic initiatives of the project, aiming to go beyond the citizens' everyday reality to increase their social-environmental culture levels in order to obtain a healthier environment for everybody, by promoting a healthy diet, the sense of caring and belonging of public space, the neighborhood historical memory recovery, the appropriate and conscious use of water sources, and the comprehensive solid waste management by means of recycling. Next, three initiatives that run today with the Communal Action Board of the neighborhood are described:

1. Agro-ecological market: it fosters health care among the residents of the neighborhood by encouraging people to consume food products –free of pesticides and chemical fertilizers- coming from the countryside. This initiative looks forward consumers to be more aware of the environmental quality of the products they eat. And –at the same time- it is expected to provide the neighborhood with a meeting place where people can reinforce the social fabric, by fostering environmental consciousness together with culture and ludic activities. Such enterprise becomes real with the contribution of the community, private companies and the public sector (See Figure 3, letters b and c).

The agro-ecological market enabled the fact that a group of farmers from the rural area of Medellin could commercialize their products directly with consumers, raising their incomes as well as their quality of life, while the people from the neighbourhood can buy healthy products. Up to June 2014, nine monthly versions of the agro-ecological market have taken place in the neighbourhood *Los Conquistadores* with the help of *Terra Biohotel*. The market is now recognized because of its approach of systemic sustainability and other neighbourhoods in the city have replicated the idea. All of this is just an alternative that promotes the responsible consumption, solidarity and collective welfare.

Figure 3 (a) Post-graduate students from Monteria, Colombia visiting the proyect, (b) Agro-ecological market and (c) Training conference about healthy diet provided by the Mayor's office within the agro-ecological market.

2. Solid waste comprehensive management: this plan intends to strengthen the resident environmental education in order to motivate them to manage solid waste rightly, to reduce waste in sanitary landfills, to avoid health problems related to the growth of unhealthy vectors, to create formal employments, to reduce the street cleaning tax for residential complexes, and to generate a prototype experience in waste management that could be replicated in another places of the city.

To develop the solid waste management in the neighborhood, there is a team who meets weekly and that is composed by the public sector: Secretary of the Environment and Natural Resources of Medellin (*Secretaría del Medio Ambiente del Municipio de Medellín),* the private sector: *Terra Biohotel,* the academy: University Colegio Mayor de Antioquia (*Institución Universitaria Colegio Mayor de Antioquia*), and the civil society: neighborhood *Los Conquistadores* residents. The work of this team is now materialized in the proposal of a project dealing with solid waste management for the neighborhood, which will be administered by the Communal Action Board, as a representation of the inhabitants.

3. Historical memory recovery: this project aims to preserve the neighborhood's identity and historical memory by means of appealing stories about the beginning, the history and the development of the neighborhood. With the narrative and visual material collected, it is expected to organize cultural events that broadcast the recognition of the neighbors with their community. Moreover, elderly population will be invited to participate in the *Terra Biohotel* initiatives concerning education in systemic sustainability (See Figure 4, letter a). Art, culture and ludic are invited to this project as facilitator elements for this idea become established (See Figure 4, letter b).

Figure 4 (a) Resident storytelling recovering and (b) Artistic exhibit in the event "Cuando el Río Suena… Arte Lleva", ("When the river sounds…there is art in it") supported by Terra Biohotel.

SUSTAINABILITY DURING THE OPERATION PHASE

Comprehensive water resources management: *Terra Biohotel* will re-use the gray water from the building to garden irrigation and hotel toilet flushing. The project has a water purified system the of the phreatic zone, which will allow a quite important level of self-supply, under the granting of a license by the authority that regulates water resources in the city. The implementation of these measures will reduced the social environmental impact that generates water capturing, processing and distribution in Medellin's water supply network and will reduce the operating costs in an approximate proportion of 30:1.

Energy efficiency: the bioclimatic design of the building structure will minimize the use of electric energy associated to air conditioning and artificial light consumption in the hotel in a proportion of 50% of a conventional energy operation in hotels of similar type and size. The hotel is provided with high energy efficiency machines, such as LED lamps, solar collectors for heating water and an air conditioning system adapted to the geographical location and climate conditions of the city of Medellin.

Comprehensive solid waste management: in the hotel operation, recyclable waste will be gathered, ordinary waste will be compacted, and organic waste will be composted to minimize the volume of solid waste dumped in the open-air sanitary landfills of the city.

Sustainable destination-hotel: the *Terra Biohotel* model of systemic sustainability management aims to organize an environmental, gastronomic, cultural, pedagogical, and patrimonial tourist offer which set the city and the region as an interesting sustainable tourist destination.

Broadcasting and sensitization: besides the commercial and economic management of the hotel project, a constant pedagogical management will be developed and will be oriented to inform the people directly interested in the project -potential clients, employees, suppliers, residents, authorities, students and professors-, so they become sensitized about the problems that the current unsustainable model has, by promoting systemic sustainability: a socio-economic and environmental balance.

CONCLUSIONS

The main contribution of this paper is the exploration of the social dimension in the systemic sustainability incorporated to the building industry, during the phases of construction and life cycle of the building . Regarding *Terra Biohotel,* it is important to remark its interdisciplinary contributions that go beyond the role of architecture and construction and that aim to reduce the environmental impact caused by construction, to achieve a strong community social incorporation and to create shared value, even in commercial uses, such as hotel industry, whose impacts are not taken into account during the planning, design and operation of a project. This environmental and social facet of systemic sustainability shows the impact of management micropolitics wills, linking the local neighbourhood management with the private sector of construction, in order to point the hotel project towards an exercise of economic sustainability, able to exceed the relation cost-benefit, supported on the environmental and social responsibility of construction.

Experiences developed and documented in this paper highlight the contributions of Terra Biohotel in a social, economic and politic context, whos management could become a proofing experience, able to contribute with environmental, social and economic analysis elements, in comparison to the problems resulting from the impact that conventional construction has, from the perspective of territorial social responsibility, glocalization, and governance, and to provide alternative solutions that influence the Colombian and Latin American reality.

ABSTRACT

This study aims to define a Zero Energy Solar-House and analyses its contribution to global warming mitigation by reducing Greenhouse Gases (GHG) emissions. This study identifies guidelines for a Solar-House project regarding electricity use, environmental conditioning, solar systems and equipment in order to obtain energy efficiency. Data to evaluate the Solar-House model are provided by Ekó House Project, which is a solar house prototype. The balance of GHG emissions reduction focus on electricity consumption, and to account avoided emissions this study considers solar photovoltaic (PV) generation instead of grid electricity, as well as energy efficiency measures harnessing the sun's energy on a passive way. This study goes through a comprehensive analysis of Brazilian electricity system, the use of electricity by the Residential Sector and GHG emissions associated. As a result, this study sets basic guidelines for a Zero Energy Solar-House and accounts the potential do avoid GHG emissions with this housing model. Benefits due to large-scale implementation of this model in Brazil are evaluated. To measure the impact of these solutions on a larger scale is taken as geographic boundary Southeastern Brazil – a region with high population density and need for importing energy from other regions of the country – where this study considers the adoption of energy efficiency measures and PV generation for a percentage of dwellings. Results show potential to avoid up to 0.9 Mt CO_2 emissions each month. From an interrelated analysis of solar PV generation and energy efficiency assessments, this study concludes that the solar-house taken as a reference has a significant potential to reduce GHG emissions, contributing to Brazil's sustainable development and global warming mitigation.

INTRODUCTION

The current economic development model considers the environment as an endless source of natural resources and final destination, with unlimited capacity to receive waste generated by human activity, embracing inefficiency and wasteful use of natural resources, especially energy, which is one of the essential supplies for the basic conditions of human life. Such model and the unbalanced operation and use of environment are the vectors of environmental problems.

Brazil is a developing country and as so, the tendency is that energy demand will increase along with the economy, implying the construction of new hydroelectric and thermoelectric plants, causing significant environmental, social and economic impacts. The residential sector consumes 26% of total

Brazilian electricity, and the increment of population purchasing power leads to an increase in energy consumption by this sector. This highlights the need to adopt energy efficiency measures and alternative and renewable energy sources, so that people can have access to consumer goods and improve their quality of life in an efficient way.

The Brazilian energy matrix is considered clean. In the National Interconnected System (SIN), 67% of energy comes from hydropower. Nevertheless, increasing concern with environmental and social impacts of the construction of new plants has been noticed. On the other hand, studies show the enormous potential for the exploitation of solar energy in the country, due to favorable levels of solar radiation throughout the year and photovoltaic systems for distributed generation are approaching an economic feasibility (EPE 2012). Therefore, it is argued that solar energy has demonstrated potential to contribute to supply this growing demand.

Given this scenario, this study aims to determine the contribution of a Zero Energy Solar-House (ZESH) to the sustainable development through energy efficiency and the use of solar energy, allowing the reduction of GHG emissions associated to energy consumption by residential sector in Brazil. To verify the potential of these actions on a larger scale, is taken as geographical boundaries the Southeastern Brazil, considering the replacement of a percentage of single-family houses by units (or systems) in the lines of the CSZE. Methodologically this study adopts a solar-house prototype, the "Ekó House", that verifies the ZESH. Thus, it is possible to predict the effective reduction of GHG emissions associated with energy use by Brazilian residential sector.

The Ekó House prototype was developed by Team Brazil, a partnership between São Paulo University and Federal University of Santa Catarina to participate on Solar Decathlon Europe in 2012. This prototype is adopted because it meets the requirements of a ZESH and simulation data regarding its energy and environmental performance are available.

GUIDELINES FOR A ZERO ENERGY SOLAR HOUSE

This study takes as dwelling unit reference a house that generates locally its own energy from PV modules. The ZESH also uses sun energy in architectural design for passive conditioning of indoor environment, reducing energy consumption. In this sense, geometries that result in elongated facades facing north and south orientation obtain a better use of the sun throughout the year. In summer, when the sun is more directly overhead, radiation is less intense on north oriented facades than is east and west oriented facades (Southern Hemisphere). In winter the sun is lower, and radiation is more intense in north oriented facades than in east and west oriented facades, as shown in **Figure 1**.

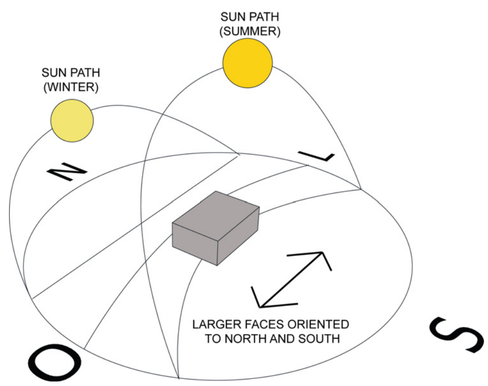

Figure 1 Solar trajectory and geometry.

The envelope elements of a CSZE have appropriate thermal performance, based on climate conditions of the implantation site, through strategies such as insulation, the use of thermal mass and/or natural ventilation. The reference prototype has high thermal insulation levels and windows properly dimensioned and positioned, ensuring natural lighting and ventilation. This results in good comfort conditions with low energy consumption by integrating passive and active strategies. Simulation models indicate a Daylight Autonomy of 60% for the Ekó House prototype (Projeto Ekó House, 2012).

In Brazil, the high investment required to improve the performance of buildings, leads people to employ low cost and low performance materials. Furthermore, there is usually no concern in adopting bioclimatic strategies to improve the thermal performance of buildings in a passive way. This implies higher energy consumption during building´s life occupancy (CANDIDO, 2010; PIRES *et al*, 2014).

In a ZESH it is essential to anticipate installation demands of solar systems, considering all components of each system on the architectural programming. The images in **Figure 2** illustrate a modular construction system and solar systems in a CSZE.

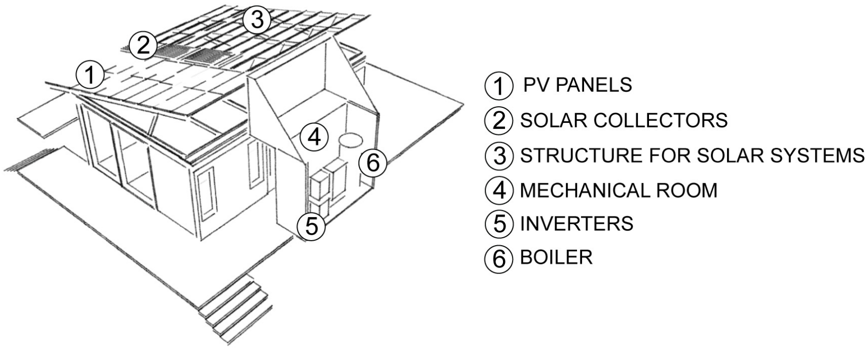

Figure 2 Solar Systems for a ZESH. (Projeto Ekó House, 2012)

The 48 monocrystalline PV panels, with an 18,5% efficiency and 11 kWp of total installed capacity generate, on average, 1.790kWh/month, enough to meet the prototype energy demand, which is around 735kWh/month, and still provide around 1.055kWh/month of clean energy to the grid (Projeto Ekó House, 2012). This positive energy balance was adopted to meet a specific purpose for which the prototype was conceived in a first moment, that is, hosting in isolated an environmentally sensitive areas in Brazil. The prototype would be connected to a local grid and could export the surplus energy to meet the demand of local facilities, like schools and healthy centers, or dwellings in these isolated locations. The graph in **Figure 3** illustrates the prototype energy balance for a typical operation year.

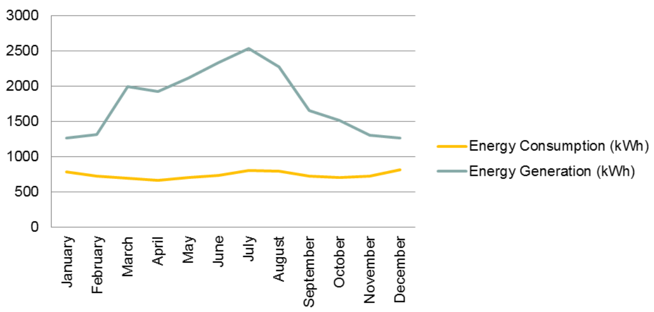

Figure 3 Energy balance for Ekó House prototype. (Projeto Ekó House, 2012)

The use of efficient appliances helps reducing energy consumption. Ekó House prototype uses National Program for Energy Conservation (PROCEL) 'level A' label. Artificial lighting, designed to complement the natural lighting, uses LED, which guarantees higher energy savings, lower maintenance and longer life. A home automation system integrated to the use of equipment and the general prototype operation contributes to a more efficient operation. This system can be programmed to guide the occupant, informing about energy generation and consumption and also control lighting and temperature, activating equipment and systems based on pre-established comfort ranges or person presence in indoor environments. **Figure 4** shows schematically the energy generation and consumption in a ZESH.

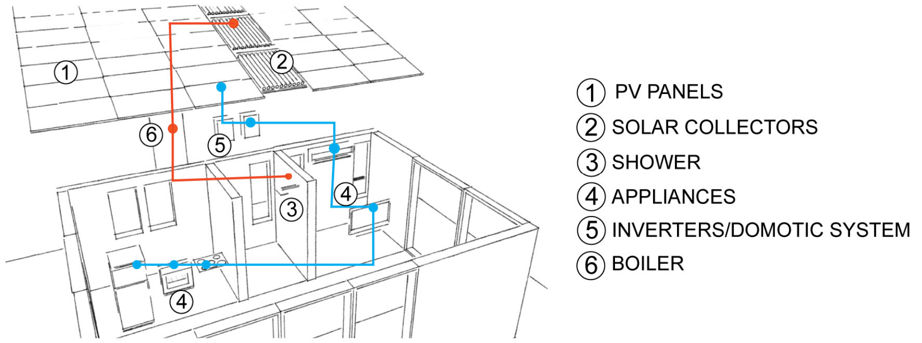

Figure 4 Energy generation and consumption in a ZESH. (From Projeto Ekó House, 2012)

ELECTRICITY SECTOR IN BRAZIL AND RESIDENTIAL SECTOR ELECTRICITY CONSUMPTION

The National Interconnected System (SIN) is a large hydrothermal system, with a strong predominance of hydroelectric plants. Only 3.4% of the country's capacity of electricity production is out of SIN, in small isolated systems located mainly in Amazon region (ONS, 2013). Hydroelectric plants correspond to 67% of energy generation, such participation enables to consider the Brazilian electricity matrix a clean matrix. Nevertheless, with the need to build new power plants to meet growing demand for electricity, more pressure comes from society and NGOs because of environmental and social impacts caused by the implementation of such new plants. Even as it is planned to extend the thermal generation in the country, including the completion of Angra III nuclear and coal-fired plants as a complement and rational diversification of usable hydropower potential naturally limited (BRASIL, 2007). It is also important to note that the losses in transmission and distribution stages reach 16.9% in SIN (BRASIL, 2012). The graph in **Figure 5** discriminates participation by source in SIN.

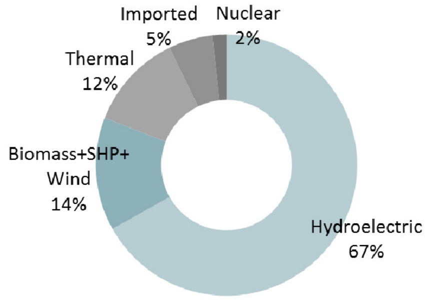

Figure 5 Participation by source in SIN. (EPE, 2012)

Another condition that highlights the need to explore other energy sources is the fact that most of the hydric resources in Southern and Southeastern are already exploited, and most of the remaining reserves are in the Amazon, away from industrial and population centers (OECD, 2001). It is important to note the potential for solar energy exploitation due to favorable annual irradiation levels in the country, ranging on average from 1.260 to 1.420kWh/m²/year (EPE, 2012). Further, the National Electrical Energy Agency (ANEEL) approved in 2012 a resolution that allows installing grid-connected PV micro-generation in dwellings.

On the other side of the equation is the electricity consumption. The residential sector accounts for 26% of total electricity consumption in the country, and it is expected that this participation will remain for the next 10 years, with an estimated increase of 48.3% by 2021. This amount considers energy efficiency measures due to use of more efficient equipment in Brazilian dwellings (BRASIL, 2012).

It is important to notice that peak demand in Brazil usually occurs by the end of the day, from 6:00 p.am. to 9:00 p.m. and is associated to use of artificial lighting, home appliances and electric shower. However, this year during the summer, new records in peak consumption were registered in Southeastern/Midwest and South SIN subsystems, as shown on **Figure 6** graphics. Such shift on peak time is associated to constant high temperature and thermal discomfort index in these regions, at the time higher insolation, which increased the use of HVAC systems (ONS, 2014).

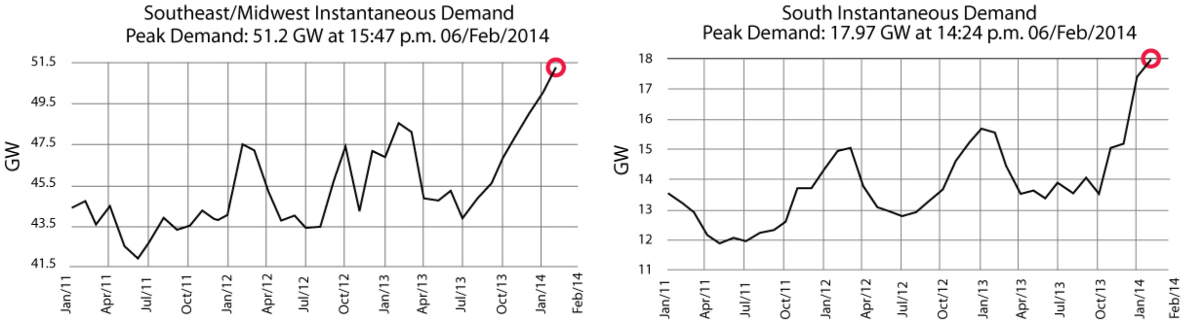

Figure 6 Instantaneous peak demand in SIN subsystems. (ONS, 2014)

Regarding the specific consumption by appliance and equipment, a research on "equipment checkout and use habits" (PROCEL, 2007) indicates the participation of different appliances in energy consumption by the Brazilian residential sector, as shows the graph on **Figure 7**. In Southeastern Brazil the average electricity consumption is around 180kWh/month for each dwelling (EPE, 2013). This indicates that there is room for increasing electricity consumption by this sector.

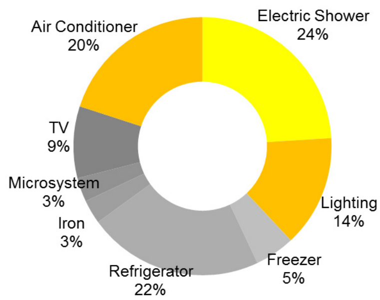

Figura 7 Participation of appliances in Brazilian dwellings. (PROCEL, 2007)

Such data regarding electricity generation in Brazil and specific consumption by the residential sector are applied to assess the benefits of a ZESH, regarding the adoption of energy efficiency measures and the PV generation by reducing energy consumption and avoiding GHG emissions.

GHG EMISSIONS BY SIN AND PV SYSTEMS

As already pointed, it is estimated that participation in electricity consumption by the residential sector will continue in the coming years, with an increase in energy consumption and, consequently, in associated GHG emissions, which must pass from 18 Mt CO2-eq in 2011 to 23 Mt CO2-eq in 2021 (BRASIL, 2012).

This study adopts the emission factor of SIN, for which the average of the last five years was 0,2926 t CO2/MWh (MTC, 2014). For the amount of greenhouse gas emissions of PV systems, are assumed values defined in the Special Report of the Intergovernmental Panel on Climate Change (IPCC), according to which the average emission factor for such systems is 0,046 t CO2/MWh (IPCC, 2012). Emissions attributed to solar photovoltaic generation are from the manufacture of photovoltaic systems and can be compensated by the manufacturer or end user.

From the combination of these data it is possible to estimate the reduction of GHG emissions that energy efficiency measures such as those adopted in ZESH and power generation by PV system can represent when applied on a larger scale.

ENERGY GENERATION AND CONSUMPTION IN ZESH

To analyze the contribution of ZESH to the sustainable development, data of Ekó House prototype are applied. Such data come from computational simulations and estimate values of generation and power consumption over a year of operation. The simulations consider developed countries comfort standards, with the presence of some appliances that, in Brazil, are not common to all population strata in the country. However, with economic development and greater purchasing power of the population, such equipment must be increasingly present in Brazilian homes, increasing the power consumption of residential sector. On the other hand, solar collectors for water heating are adopted and artificial lighting uses only LED. The graph in **Figure 8** shows the monthly consumption in Ekó House prototype.

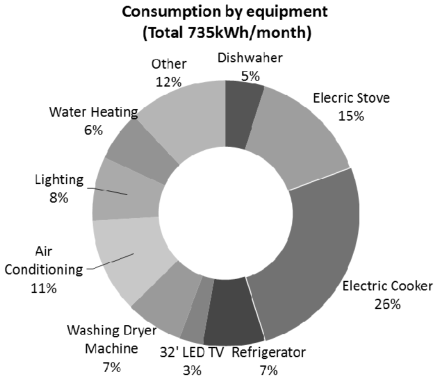

Figure 8 Consumption by equipment in Ekó House prototype**.** (Projeto Ekó House, 2012)

By comparing the simulated consumption for the prototype of 735kWh/month, with the monthly average consumption of households in developed countries such as the United States, which consumes on average 958kWh/month (EIA, 2011) per dwelling, is possible to realize that even keeping comfort levels of these countries, the prototype reaches more efficiency in electricity consumption.

To estimate the reduction in energy consumption, this study considers the adoption of solar collectors for water heating in Brazil. It is assumed that 70% of the annual demand for hot water is provided by solar collectors. Thus, the reduction in power consumption obtained is approximately 17%. Assuming that an appropriate use of the sun for daylighting and passive conditioning associated with the use of LED system and passive thermal conditioning strategies, contribute to energy efficiency with a 30% saving in consumption by air conditioning and artificial lighting systems. Thus, another 10% of total consumption would be avoided, as shown in **Figure 9**.

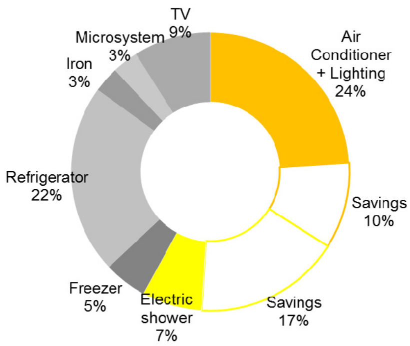

Figure 9 Energy savings for harnessing solar energy.

ZESH CONTRIBUTION TO REDUCE ELECTRICITY CONSUMPTION AND AVOID GHG EMISSIONS

To demonstrate the contribution potential of harnessing solar energy in architecture, it is taken as geographical boundaries the Southeastern Brazil, which has about 20 million households, of which approximately 80% (or 16 million) are single houses (IBGE, 2010). To account the contribution of using solar PV, it is considered that 50% (8 million) of single-family houses would adopt PV micro-generation system, similar to Ekó House, but a lower cost system to be economically viable. With PV generation, avoided emissions could reach 0.2926 kg of CO_2 for each 1.0 kWh generated. Assuming a PV system with 24 polycrystalline modules, with a 13.5% efficiency and a 3.24 kWp installed capacity, the generating would be on average 387 kWh, considering the data for São Paulo, according to RETScreen® 4 software simulation. Thus, avoided GHG emissions in SIN would be around 113 kg of CO_2/month per household, or 0.9 Mt CO_2/month considering the adoption of this PV system in 50% of single houses in the Southeastern, totaling 10.8 Mt CO_2 per year.

According to a financial analysis, simulated also on RETScreen® 4, such system would have a price around 0.35 R$/kWh, without considering incentives, which is close to the average electricity tariff in the country of 0.32 R$/kWh (ANEEL, 2014). It is also important to notice that some studies already point to an economic viability of PV systems for distributed generation in Brazil (EPE, 2012).

Taking into account the average dwellings consumption in the Southeastern, 180 kWh/month, and the projected increase in consumption of the residential sector in the ten-year horizon, the average consumption is expected to reach 270 kWh/month in the coming years. With the values assumed for energy savings through solar energy use, this consumption could be reduced by 27%, resulting in a consumption of 197 kWh/month. Such measures would contribute to stabilize consumption on a decennial horizon, even improving comfort conditions in dwellings. Thus, on average, 190 kWh/month would be delivered to the grid by each household with the PV micro-generation system, or 1520 GWh by installing micro-generation in 50% of single houses in the Southeastern, avoiding up to 0.44 Mt CO_2 of emissions per month in SIN. Still, not considering the PV generation, and considering the harness of the sun, as described above, could save 27% on energy consumption, and this would represent a reduction of about 73 kWh/month per household, or 584 GWh for 8 million dwellings, avoiding 0.17 Mt of GHG emissions.

The graph in **Figure 10** illustrates the emissions avoided by PV micro-generation in single house units and the adoption of energy efficiency measures focused on harnessing solar energy, through projections to the Southeastern Brazil. The added value comes when the manufacturer is responsible for offsetting GHG emissions from the manufacturing of PV systems. In this case, the SIN emissions factor is adopted to account GHG emissions avoided. But when the consumer assumes such compensation, the emission factor applied is the one for SIN discounting the PV systems emission factor.

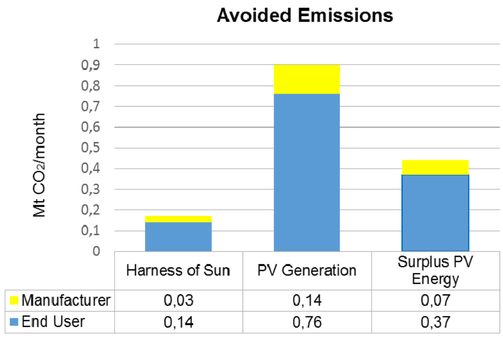

Figure 10 Potential to avoid emissions in the Southeastern Brazil through ZESH.

The study considered that the increase in consumption by the residential sector will be made according to PDE 2021 predictions. Nevertheless, this projection was made taking into account a consumption which also expresses a pent up demand for electricity in the country. With a PV with an installed capacity such as the one adopted for this study, it would be possible to reach better comfort conditions, supplying this demand with a clean and renewable source, without additional GHG emissions.

The PV generation in locations where single houses are a predominant typology can contribute to meet the demand on the network at times when other sectors require more energy than residential, like the commercial sector during daytime. The records on peak consumption during summertime point that electricity demand in SIN is increasing during daytime. This highlights that PV systems adopted on a large scale would contribute to supply electricity demand in SIN and avoid GHG emissions, by exporting energy clean energy to the grid. The use of solar collectors, LED system and the adoption of passive conditioning strategies contribute to reduce the demand for electricity at regular peak consumption time in the end of the day, when electricity demand increases in dwellings due to the use of artificial lighting, thermal conditioning systems and, specially, the electric shower.

CONCLUSION

This study demonstrates that a ZESH can make a decisive contribution to sustainable development. The combination of solar systems and energy efficiency measures demonstrates high potential to contribute in meeting the demand for electricity in the SIN through PV generation, and it also contributes to reduce demand at electricity consumption peak time.

From the projections made in this study, it is possible to conclude that energy efficiency measures help to avoid GHG emissions, mainly in the case of ZESH. The expected increase in demand for electricity by residential sector allows us to observe the relevance of such measures, in order to improve population's comfort and welfare without necessarily increase electricity consumption. However, the PV generation demonstrated an even greater contribution on avoiding GHG emissions, especially when there is surplus electricity generation that can be exported to the grid.

In short, the ZESH demonstrates potential to contribute to sustainable development of the country and use of solar energy proves to be essential inasmuch a long-term reliability on non-renewable sources can be considered unsustainable economically, socially and environmentally.

ABSTRACT

Growth of cities and rising occupant comfort expectations has led to an increasing cooling demand of buildings. The use of solar energy for the production of electricity with photovoltaic modules and hot water with solar collectors is a common application. Operating the PV-T collectors at night is the possibility given to cover the cooling demand with a renewable energy source; radiative cooling. This paper focuses on the potential analysis of PV-T collectors for heating, cooling and electricity production for 6 different climate conditions. First the state of the art, four different PV-T technologies and two examples for building integration are presented. This new prototypes of PV-T collectors with different joining methodologies between the absorber and the PV module have been developed and tested at an outdoor test stand under dynamic conditions. Measurements of these four new collector types are shown and compared with a TRNSYS PV-T collector model. Finally a potential analysis for heating, cooling and electricity production for one of the developed PV-T collector was carried out under different climatic conditions. The simulation results showed that this PV-T collector has the highest cooling potential in cold and moderate climate zones where cooling is needed only temporarily. In hot and humid climates where cooling is needed over the whole year, the cooling potential of the PV-T collector for radiative cooling is less. The increase of electricity production by cooling the PV cells varies between 0,1 and 5,8 %, depending on the inlet temperature and the weather conditions.

INTRODUCTION

Hybrid PV-T (photovoltaic/thermal) collectors usually are used for heating and electricity generation. The combination of both technologies can save valuable building surface space (e.g. roof, facade) for solar installation because of the twofold use, while meeting all the energy demands of a consumer. Moreover, this technology enables retaining the efficiency of PV modules, due to the cooling effect of the thermal fluid on the PV cells, which prevents their overheating degradation. Recently, the possibility of cooling applications of PV-T collectors are being investigated where radiative cooling is employed based on long-wave radiation losses from the roof surface (for example) towards the sky driven by surface temperature difference. On a clear night, cooling capacities of 50-120 W/m² can be reached (Cremers et al., 2010 and Beck & Büttner, 2006). New PV-T-collectors have been developed and installed in the building “home^{+}” for the international competition Solar Decathlon Europe 2010 in Madrid, Spain, see section 3. The authors are currently improving this system within two research projects. The goals of the study are is to examine different technical solutions to build such PV-T collectors, to optimize and measure the thermal and electrical performances and to show possibilities for building integration with regard to architectural requirements.

Author A is a research fellow at the Centre of Integral Architecture and Authors B at the Centre of Sustainable Energy Technology. Author C is a professor in the Faculty Architecture and Design and program director for the course "KlimaEngineering" and D is a professor in the Faculty Building Physics and program director for the course “Sustainable Energy Competence“.

1. PV-T TECHNOLOGIES AND STATE OF THE ART

A PV-T collector is a combination of a thermal absorber and a PV module that can be joined together in different ways. In this section the joining technologies are presented, along with an overview of the classification, historical background, and current market for PV collectors.

1.1. Classification of PV-T collectors

According to the IEA SHC Task 35, PV-T systems can be mainly classified into flat-plate air collectors, flat-plate liquid collectors, concentrating PV-T collectors and ventilated facade integrated PV-modules (Hansen and Sorensen, 2006). PV-T air collectors usually generate electricity that is used only to drive the ventilator and not for feed–in to the net; in this case, solar cells occupy only a small part of the collector aperture. Within this paper only water-based uncovered flat-plate collectors will be investigated and presented. Water-based flat plate collectors can be divided into covered and uncovered collectors (Figure 1). The difference between uncovered and covered PV-T collectors is that the latter are comprised of a top cover with an air gap to the absorber to reduce the long wave radiative heat transfer and convection losses.

Uncovered PV-T collectors usually have a glass or foil protection that belongs to the PV module. The most promising application for this type of collector is radiative cooling during the night because of higher radiative heat transfer due to the absence of a top cover. Covered collectors are more suitable for domestic hot water production and heating since higher fluid temperatures can be reached. However, higher temperatures within the module decrease the electrical efficiency of the PV cells - the cell efficiency decreases up to 0,5% per 1K temperature rise (Weller et al., 2009). To avoid this decrease in cell efficiency, the module has to be cooled by a fluid, which means that the system needs a consumer load to discharge the heat, see section 4.3.

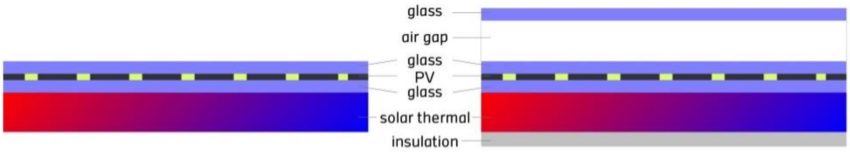

Figure 1: PV-T flat-plate liquid based collector uncovered und covered (PV on absorber area)

1.2 Historical Background

First investigations on PV-T collectors started after the oil embargo 1973/74. The focus was basically to decrease the consumption of fossil fuels and as most applications require both electricity and heating, thermal and electrical parts were combined.

Consequently, there was a need for further research in order to optimize the combination of both technologies. H.A. Zondag summarized in 2008 the historical development of PV-T collectors. The first works on PV-T liquid collectors were done by Martin Wolf in 1976 (Wolf, 1976, Zondag, 2008 and Hendrie, 1982). At the beginning, most of the research was done in the USA (and some in Japan), but in 1979 Karl also published his studies on the development of a PV-T collector in Germany (Karl, 1979 and Zondag, 2008).

Meanwhile, investigations were made to use radiative cooling towards the night sky to cool down water and also air or to discharge thermal mass on the roof (Erell, 2007). One of the first water-based radiative cooling systems was investigated by Juchau (1981). He used a regular solar thermal system for heating purposes to cool down water of a thermal storage tank during the night by circulating it through a standard flat plate collector. During the day, this water was used to cool a building through a radiant floor. In further investigations in Israel, the top-cover of a standard flat-plate collector was removed to increase the cooling power (Erell & Etzion, 1992).

The application of PV-T collectors for night radiative cooling has not yet been thoroughly researched, to the knowledge of the authors. PV-T collectors are becoming better known for cooling applications through the international competition series of “Solar Decathlons”. Various building concepts with PV-T collectors for cooling purposes, such as the home+ building from the University of Applied Sciences of Stuttgart (Eicker & Dalibard, 2011), have been constructed.

Among the obstacles that constrain the promotion of PV-T collectors on the market is the absence of a corresponding standard for this combined technology. Solar Keymark provides a certification method for uncovered PV-T collectors based on existing standards. Within this certification the PV and Solar Thermal part are tested separately; the electrical performance of the PV part according to IEC 61215 or IEC 61646 and IEC 61730 and the thermal performance according to EN 12975-1 and EN 9806. During the thermal performance test, whether the PV module is operated under MPP, OC or SC condition must be indicated, since the efficiency of the thermal performance is influenced by the electrical part. In contrast, covered PV-T collectors are potentially not covered by the above mentioned standards since they are able to reach much higher stagnation temperatures and therefore potentially will not pass the PV standards (Fritzsche, 2013). In order unify standards for the PV-T collector, the research project “PVT-Norm” (Standardization of PV-T collectors) is being carried out (Bine, 2013).

1.3 PV-T collectors available on the market

Currently, approximately 27 manufacturers are known to produce uncovered PV-T collectors with or without thermal insulation and different technical solutions. Some manufactures produce also only a thermal part of a collector that can be mounted on the back of a PV module as a retrofit. The PV module can be therefore exchanged when needed. The producers of covered PV-T collectors are not so numerous; only 5 manufactures could be identified. PV cells in a covered collector can be attached either on the absorber or on the inner side of the covering. A PV-T collector with vacuum tubes is currently being developed by a company in England, but it has not yet been commercialized.

1.4 Prototypes within the Project

Within this project, different possible combinations of materials are investigated. The aim is to develop a collector that has very good performances and is cost-effective. For this purpose, different collector variants have been built and mounted on an outdoor test stand to characterize their performances in order to evaluate the best material combination and bonding technique, and to compare the results with commercially available products.

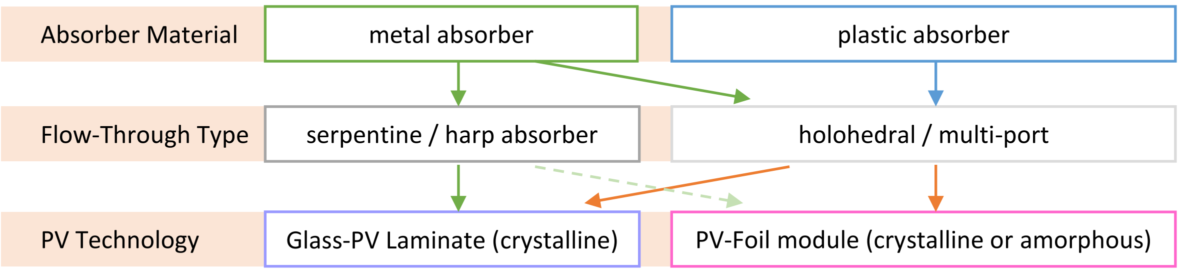

Figure 2 Different material combinations investigated

There are many possibilities of PV and absorber combinations including laminated or flexible modules with crystalline or thin film technology, both in combination with a normal deflector plate and pipe installation or holohedral flow through plastic or metal absorber, see Figure 2. The constructive aspects of PV-T collectors that have an impact on the thermal performance are mainly the thermal bond between the PV module and the thermal absorber (e.g. lamination, pressing and gluing) and the thermal resistance of the PV module itself, both of which are dependent upon the design and the manufacturing possibilities. One of the most critical properties is the thermal expansion coefficient of the PV module and thermal absorber. Consequently, the connection has to be flexible enough to balance the forthcoming dilatation of the chosen materials in addition to a small thermal resistance. Besides the thermal performance, there are other important aspects such as costs, durability and recyclability that should be considered with a new collector design.

In this paper, the following PV-T prototypes are presented (Figure 3):

Type 1 uses a polypropylene holohedral absorber fixed in the frame on the back side of a glass-PVB laminated PV module. The PV and the absorber are only pressed together.

Type 2 features the same construction as Type 1, with the difference that the polypropylene absorber is fixed with an air gap to the PV module. This simulates the building integration on a sloped roof when thermal and PV components are mounted separately

Type 3 is a laminated glass-PV-absorber module with a serpentine copper absorber. The copper tubes and the aluminum absorber are bonded to the PV module back side with heat conductive silicon glue.

Type 4 is a polypropylene holohedral absorber pressed against a laminated glass-PV-glass module with aluminum U-profile in diagonal, providing more contact zones.

Type 5 is almost the same as the Type 3, the only difference is the PV module. In this case, a laminated glass-PV-glass is used. This increases the thermal resistance between the PV module and the absorber.

In section 4, the measurements results of collector type 1-4 are presented.

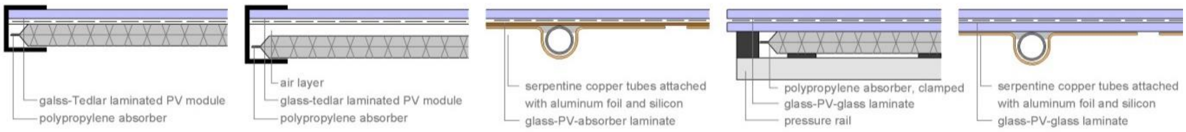

Figure 3 PV-T Prototypes 1, 2, 3, 4 (Ecolar) and 5 (home+)

3. BUILDING INTEGRATION

The type of integration of PV-T modules depends on the application and on the surrounding neighbors. One building integration requirement for a high thermal efficiency for cooling purposes is a good view angle to the sky (180°), which indicates the absorber area is as horizontal as possible. Moreover a higher building next to the PV-T area causes a reduction of the view angle, which results in a smaller radiative heat transfer rate. For cooling applications, the heat losses of the PV-T collector have to be maximized. Therefore an uncovered, uninsulated and well ventilated PV-T module is the most pertinent design. For heating purposes and electricity generation, the PV-T collector performs better if it is inclined to a certain angle, depending on the latitude of the location. However the higher the inclination is, the lower the night time radiative cooling performances are.

Consequently, a compromise must be found between cooling and heating applications. For example, cooling of the PV cell improves electrical performances, which may thereby allow for some deviation from the optimal inclination / sun orientation angles.

Figure 4 (a) Ecolar, 40m² PV-T and (b) home$^+$ (with 100m² PV thereof 36m² PV-T) and (c) detailed section of the roof of home+

Uncovered PV-T prototypes were installed on the roof in two buildings; the Ecolar building (Figure 4a) and home$^+$ building (Figure 4b), collector type 4 and type 5, respectively. In home$^+$, the PV-T modules are mainly used for cooling purposes (Cremers et al., 2010), while in Ecolar they are also used for warm water preparation. Despite the different collector designs, the collectors are both integrated on the flat roof. The PV-T collector area in home+ are totally horizontal with black monocrystalline cells and a white back sheet (module size 2,60x1,20m). In the Ecolar, the PV-T collectors are slightly sloped with black monocrystalline PV cells but with a black back sheet (1,03x4,28m). Here the PV-T area is also the water-drainage layer and a post-and-beam construction was chosen (HTWG, 2012). In home$^+$, the rain water from the PV-T surface flows between the gaps of the PV-T modules to the waterproofing layer underneath, where the water is diverted from the inclined plane as depicted in Figure 4c. According to the building simulation of home$^+$ presented by Eicker and Dalibard (2011), 43% of the cooling loads can be covered by the radiative cooling system in combination with a 1.200 liter heat sink tank for the location of Madrid.

Depending on the constructive integration level (e.g. addition, substitution, integration) (Weller et al., 2009), market available PV-T Modules are suitable for all possible building integration methods, such as in-roof mounting on pitched roofs.

4. TEST STAND RESULTS AND POTENTIAL ANALYSIS FOR SIX DIFFERENT CLIMATE LOCATIONS

As described above, PV-T collectors can be used to produce solar hot water and chilled water. At the University of Applied Science in Stuttgart (Germany) an outdoor test stand for the performance analysis of PV-T collectors was set up. The measuring process for the characterization of the PV-T collectors is based on the quasi-dynamic test method for uncovered thermal collectors of the new EN ISO 9806:2014. All important boundary conditions like wind, temperature, global radiation and longwave radiation were continuously measured and recorded. The collector field inclination at the test stand can vary between 0° and 90°, considering this roof and facade systems can be tested closely to their application. The presented measurements in the next section were carried out with an inclination of zero degrees and a collector inlet temperature near the ambient temperature.

4.1 Experimental measurements and evaluation of the results

In order to analyze the performance of the different collectors, collector types 1 to 4 have been tested simultaneously under dynamic conditions. Figure 5 shows the measured global radiation, ambient, inlet and sky temperature during the test period. The corresponding thermal power output for two days in May is presented in Figure 6.

The analysis of the measurements shows that collector type 3 performs best at day-time where the fluid is heated up and collector type 1 performs best at night-time where radiative cooling is dominant. Collector type 2 has the lowest power output at day- and at night-time, which could be explained by the high thermal resistance between the PV and solar thermal absorber caused by the air layer between the PV module and the solar thermal absorber. The thermal efficiency varies between 25 (for collector 2) and 48 percent (for collector 3). The efficiencies are low compared to standard covered flat plate collectors, which can reach efficiencies up to 80 percent during day-time. However, as before mentioned an additional glazing is counterproductive for radiative cooling application.

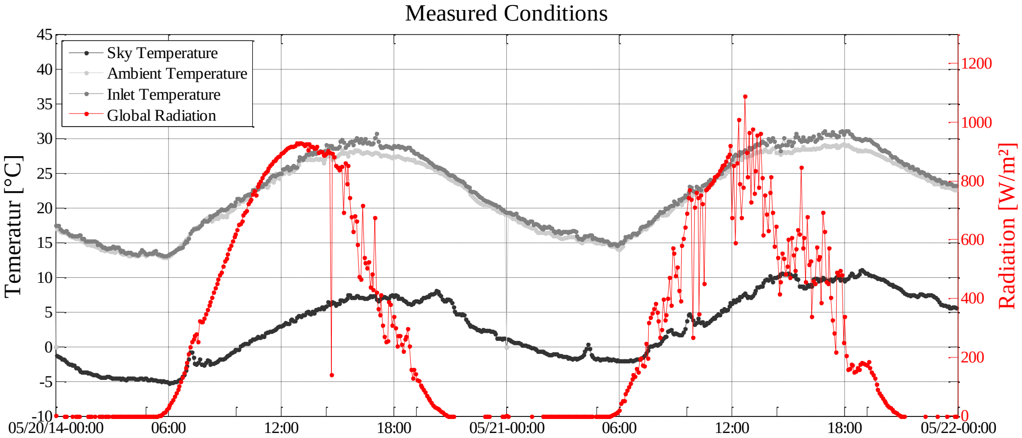

Figure 5 Measured thermal weather conditions (Stuttgart / Germany 20.05.2014 – 21.05.2014)

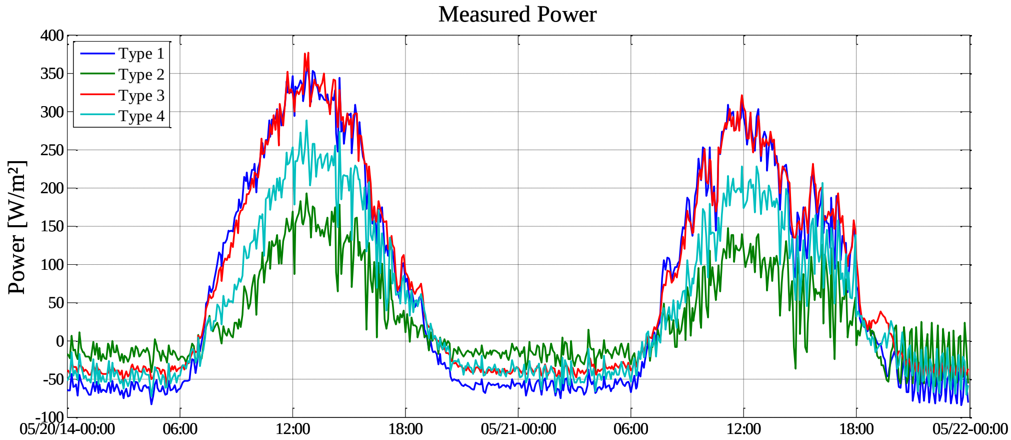

Figure 6 Measured thermal power of the collector types 1 to 4 (20.05.2014 – 21.05.2014), with an test stand inclination of 0 degrees

4.2 Climatic information for six different climate zones for the heating and cooling potential analysis

Weather data at the specific locations should be analysed in order to draw conclusions about the energy production of PV-T collectors without considering a whole building as a consumer. A common method for the calculation of heating and cooling periods from weather data files is the calculation of heating and cooling degree days (HDD and CDD). The degree-day method can be used to define the time period when cooling demand in a building is needed. The calculation is typically based on daily mean ambient temperatures. However, air conditioning systems are often turned on and off during unoccupied periods, therefore cooling degree hours or cooling degree periods better present the cooling demand. For the calculation of the CDD was obtained from the ASHRAE standard (ASHRAE. 2009) (Equation 1). The weather data for the locations was taken from Meteonorm Software (www.meteonorm.com) and represent long time mean values of the climatic conditions.

$$CDD = m_k \sum_{k=1}^{365} (T_{e,k} - T_{tc}) \qquad (1) \qquad m_k = \begin{matrix} 0 & if\ T_{e,k} < T_{tc} \\ 1 & if\ T_{e,k} \geq T_{tc} \end{matrix}$$

Where $\boldsymbol{T_{e,k}}$ is the mean external temperature at the k period of the year, $\boldsymbol{T_{tc}}$ is the threshold temperature for cooling (here 22°C). Table 1 shows the calculated cooling season, the *CDD*, the mean and standard deviation of the ambient and sky temperature for daily occupation periods from 11am- 7pm for six different climate zones as defined by Hausladen, Lied and Saldanha (2011).

Table 1. Calculated cooling season for daily occupation periods from 11 am – 7 pm

Location	Cooling season	CDD [Kd]	Mean ambient temperature and standard deviation	Mean sky temperature and standard deviation
Moscow (cold climate)	20 May – 04 Sept.	102	17,9 / 4,5	10,2 / 7,1
Stuttgart (moderate climate)	11 Apr. – 04 Sept.	155	16,3 / 5,9	7,9 / 8,4
Shanghai (subtropical)	07 Apr. – 22 Oct.	997	24,2 / 5,1	18,5 / 7,5
Chennai (tropical)	01 Jan. – 31 Dec.	3803	29,1 / 3,8	23,1 / 4,6
Dubai (coastal desert)	01 Jan. – 31 Dec.	3617	28,4 / 6,6	18,3 / 8,0
Riyadh (continental desert)	01 Jan. – 31 Dec.	3843	27,3 / 9,4	8,3 / 10,2

4.3 Simulation model verification and potential analysis of one PV-T collector with different inlet temperatures

This section deals with the quality of the simulation model employed and the potential analysis for heating, cooling and electricity production of collector type 3. The decision to use collector type 3 for the simulation study was based on the available data for this PV module and its better aesthetic for building integration (see Figure 4b). Type 203 of TRNSYS, which was developed at the Institute for Solar Energy Research Hameln (ISFH) / Germany (Stegmann, M. & Bertram, E., 2011 and Bertram, E. & Stegmann, M., 2011), was used to simulate an uncovered photovoltaic-thermal collector not only for heat and electricity production but also for radiative cooling application. Equation 2 shows the energy balance for the fluid implemented in Type 203 of TRNSYS. The electrical part is modelled according to EN 60904 and the thermal part according to EN 12975.

$$c_{eff}\frac{d\vartheta_m}{dt} = \dot{q}_N - E_n{}^{*}\eta_0(1 - b_u u) + (b_1 + b_2 u)(\vartheta_m - \vartheta_i) \qquad (2)$$

Where $\boldsymbol{c_{eff}}$ (kJ/m^2 K) is the effective collector heat capacity, $\boldsymbol{\vartheta_m}$ is the mean fluid temperature and $\boldsymbol{\vartheta_i}$ the ambient temperature, $\boldsymbol{E_n}^*$ (W/m^2) is the incident angle-corrected irradiance, $\boldsymbol{\eta_0}$ is the conversion factor, $\boldsymbol{u}$ (m/s) is the wind velocity, $\boldsymbol{b_u}$ (s/m) is the wind dependence factor for η_0, $\boldsymbol{b_1}$ (W/m^2 K) is the heat loss coefficient, $\boldsymbol{b_2}$ (J/m^3 K) is the wind dependence factor for $\boldsymbol{b_1}$, $\boldsymbol{\dot{q}_N}$ (W/m^2) is the specific thermal collector output power. The parameters for Type 203 were calculated from the measured data shown in the previous section (Figure 5 and 6) and validated against a third day. The identification of the parameters was done by adjusting the coefficients in Equation 2 that best reproduce the measurements. Figure 7 shows the measured and simulated return temperature and power output for the collector type 3.

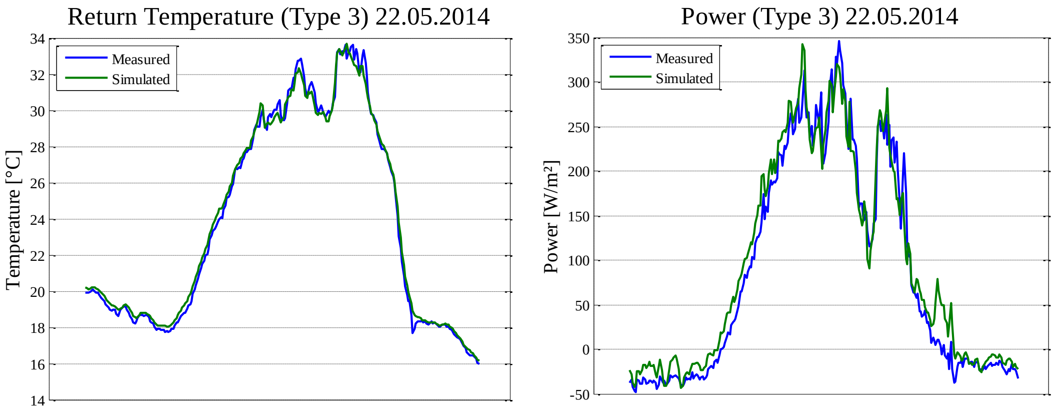

Figure 7 Comparison between measurement and simulation for temperature (l) and power (r)

For radiative cooling applications the view factor toward the night sky of the collector is very important. In this study the angle of the collector was fixed to 0° (full view to the sky), the mass flow was set to 40 kg/(m²h) and the inlet temperature was set to the collector to 25, 35 and 45°C. These inlet temperatures were chosen because they represent typical operating temperatures for systems like cooling ceilings and heat pumps.

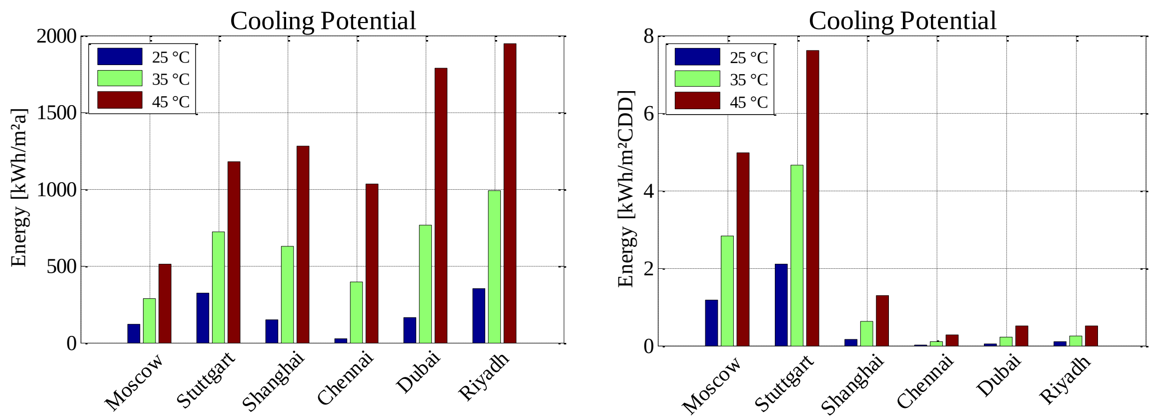

Figure 8 Simulated absolute cooling potential for the cooling season (left), cooling potential per CDD (right) for the collector Type 3

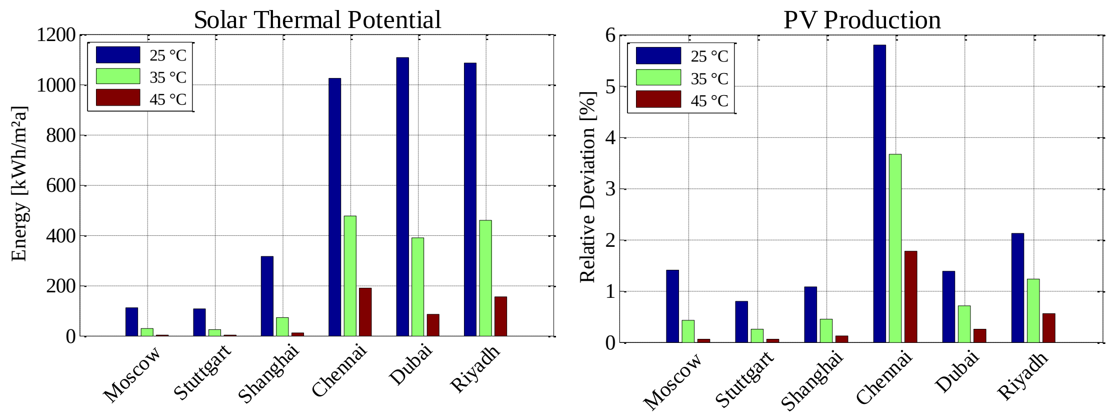

Figure 9 Solar thermal potential (left) and relative deviation for the PV production (right) for the collector Type 3

Figure 8 presents the simulation results of the cooling potential and Figure 9 the solar thermal potential and relative deviation for the PV production depending on the location and the inlet temperature. The results show a strong increase of the cooling potential with the rise of the inlet temperature. This is caused by the increase of the convective and radiative heat losses to the ambient and sky, respectively. The highest absolute cooling potential was calculated for Riyadh and the lowest for Moscow with an inlet temperature of 45°C. However, the highest cooling potential per cooling day could be found for Stuttgart and Moscow. The highest solar thermal potential is in Dubai and the lowest in Moscow, with an inlet temperature of 25°C. The highest increase in PV (electricity) production with 5,8 % was found for Chennai and the lowest with 0,1 % for Stuttgart.

4.4 Discussion of results

The cooling potential per *CDD* values presented in this simulation study particularly show high values for cold (Moscow) and moderate climate zones (Stuttgart). However, the highest absolute values can be reached in continental desert zones (Riyadh). Although the cooling season in Chennai is of the same length as in Riyadh, the absolute cooling potential is lower. This could be explained by the lower ambient and sky temperatures of Riyadh compared to Chennai, as presented in Table 1. The new prototypes presented in this paper are uncovered on the top side and uninsulated on the backside. A combination of PV-T collectors with heat pump systems could provide a higher temperature inlet temperature level to the collectors. For the design of a system that includes PV-T collectors, all three aspects, PV production, solar thermal and cooling potential, need to be considered simultaneously. However, the use of PV-T collectors in a system needs to be studied in more detail, especially the integration and the dimensioning of the system. For Chennai, Dubai and Riyadh where heating is not necessary, further research might be directed to find suitable applications for the gained energy during day-time.

5. CONCLUSION

First results show a good match between the simulations and measurements for the analyzed collector. Results prove the potential of the described PV-T collector approach to provide thermal, electrical and cooling applications, which is different from the common application of current or historical use of PV-T products on the market today. Large differences exist in the usage potential in different climatic zones as it has been described and reflected in the PV-T collector design with regard to its technical detailing and its costs, which are highly dependent on the materials, components and manufacturing technology. It is expected that a low-cost approach focusing on an optimum performance on the cooling side has the highest applicability in the areas with the highest overall performance. Another issue will be the integration of these PV-T collectors in buildings with regard to an appropriate supply system (e.g. cooling and heating incl. storage, DHW, electricity) with robust control systems and architectural design requirements.

aysegul.tereci@karatay.edu.tr

Dilay Kesten Erhart, PhD
[Stuttgart University of Applied Science]

ABSTR ACT

In tandem with industrialization, migration from rural to urban has caused unstructured and unplanned cities. On the other hand the needs of people in the cities have begun to change according to overpopulation, new technologies and life styles. This change results in growing energy demand at the cities and the governmental authorities and municipal services has to respond it. Urban transformation projects are given as a solution for struggling with these problems and reshaping the cities. Energy, one of the main topic on the urban transformation projects, contains the efficient resource and energy management, minimization of the energy consumption as far as possible and capacity enhancement for renewable energy sources. While developing urban transformation projects, the optimal and effective solutions should be investigated for the project area having regard to applicability, environmental impact, and economical feasibility. In this research, the energy demand profiles of generic residential urban blocks for two city locations in Germany and Turkey are simulated using EnergyPlus to identify the site density and physical properties effect moreover the significance of site design on future renewable energy integration opportunities. The research shows that 10-20% energy demand can be saved by an energy aware site planning and the urban transformation projects also have a big potential to supply more than 30% of the energy used with renewable energy sources.

INTRODUCTION

At the end of the 19th century with industrialization, many people began to live in the cities which are the centre for trade, industry and transport. Migration from rural to urban area has gained accerleration with education and business opportunity in middle of 20th century. Today half of the world population lives in cities and it is predicted to increase to more than %65 by 2050 [UnitedNations, 2008]. Nowadays, cities are the overpopulated sharing place of all networks such as transportation, services, finance, social spaces, cultural links, etc. Therefore management of all networks in cities is concerned with configuring, efficiently and equally supplying of the resources to the citizens and ensuring the continuity of the cycles for sustainability.

Especially in Europe, cities have been developed over hundreds years ago. Zonning, structure and network systems were consisted with industrialization but nowadays the European cities are transformed to management centers with head quarters of many firms so cities have to be globalized with sharing network and they need additions or refurbishment for information age [Thorns, 2002].Another point worth mentioning is that new poor citizens (not in Western Europe but rest of the World) who came to city with hope of job placement, solve their residence problem by ownself and living area capacity of the

Dr. Ayşegül Tereci is an asisstant professor in the Department of Architecture, KTO Karatay University, Konya, Turkey. Dr. Dilay Kesten is a researcher at Stuttgart University of Applied Science, Stuttgart, Germany.

city has been increased many times without planning or structuring the new development areas. It is estimated that by the year 2035 half of the world poor population will live in this unplanned areas [Horwood, 2007]. It means that this population will begin to live in unstandardized building blocks with lack of infrastructure and with insufficient supply mechanism. It is big challenge to struggle with this problem for city managers.

Besides that, life style in cities and the technology has metamorphosed the demand of people. Industrial production and modern-day consumers with increasing wealth require more energy for daily needs. Basically all international and national governmental or local authorities deal with this energy management problem. On the other hand authorities have an important role on reducing green gas emissions and climate change mitigation. There is a big opportunity to make a cost effective saving in the energy demand of city building stock and provide the sustainable environment development for cities.At this juncture, sustainable urban development becomes even more important for future of urban life. Sustainable development first appeared in the literature during the 1970s and 1980s and early 1990s the issue of sustainable development gained momentum. After the United Nations' Rio Conference's Agenda 21, sustainable development is preferential as policy for every urban authority (Beatley and Manning, 1997). Many projects and programs are going on for sustainable or energy efficient cities on the world and especially European Union level (Concerto, Civitas, Urbact, Energy Cities, etc.) [http://www.eumayors.eu/about/related-initiatives_en.html]. Reconstruction, renewal or transformation projects can be the solution for urban quarters.

One of the most common sustainable urban development strategies is transformation of the city's quarters. Urban transformation projects are kind of solution for unplanned or unusable urban areas. It is physical transformation for existing building stock with new standards and also it provides better structure to public space and supply network. For developed countries like Germany, it is way to alter the unusable area with new technology integration and to mitigate the impact of climate change. For developing countries like Turkey, urban transformation projects change the physical environment and especially urban spatial structure and begin to control building standards. After having lost thousands of people in earthquake in the past, before even worse disasters hit the country, unplanned cities with buildings out of keeping standards should be transformed in Turkey.Transformation projects are significant for integrating strategies and aspects for energy management of authorities. It has big potential to integrate efficient resource and energy management principals, to minimize the urban enegy consumption and to adapt the renewable energy sources. Chief point for this energy transformation acts is that affordable and adaptable solutions should be determined for the urban sites. Sustainablity of the developing areas has to be considered for present and future users.

In urban projects, the steps and strategies are important for implement and handle the project as a result of the largeness of the area. If the project developer has an approach for different sites and it is applicable for different area, it can be used for various places. This research takes the common points for all urban transformation projects such as density, building property and possible renewable energy sources. It clarified the steps for this urban energy transformantion project and prose a practicable approach for the projects.

FACTORS AFFECTING THE URBAN ENERGY IN TRANSFORMATION PROJECTS

In the urban scale studies, to know the patterns of energy consumption is important for the management of supply. In the energy management works, it is easy to get information from supply but it is hard to define the requirement for different energy sources and the nature of users' requirements. This kind of energy information is significant for sustainable urban energy planning, for the reason that the energy supply needs to be on meeting energy users' needs in the best way possible. Urban design pattern mainly draw the city line and it shapes the inhabitant's comfort requirement or requests. On this level architecture or city planning doesn't have a comprehensive model which can be applied to every place and can take all factors on the account for developing sustainable cities or settlements. But we can define the main factors that affect the urban energy consumption and shape with urban design decision. These factors can be categorized as follows:

Urban density

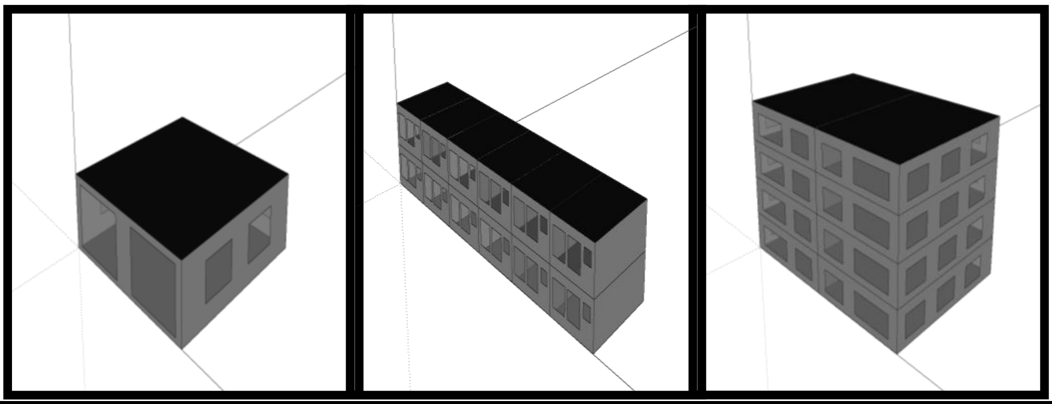
Rapid population growth brings with it, a growing need for built-up area which is one of main problems of the cities. Most of the time, this need is proved with high-rise buildings or compact settings, instead of expanding the boundaries. This brings the term of "urban density" which is used in urban planning and urban design to refer to the number of people inhabiting in a given urbanized area [Sokido and Bhaduri, 2013]. The urban density can affect the total energy demand of a city with different ways and these effects are complex and conflicting [Givoni, 1998]. Density sometimes can bring the benefits but it also creates extra loads and undesirable conditions. It affects the thermal performance, the natural lighting and ventilation possibilities of the buildings and these effects can either be positive or negative according to dominant climatic condition. On the other hand, the density supports to the district energy systems and besides that, the infrastructure facilities are shorter so it reduces also the energy requirement for pumping. Controversially, the energy requirement for pumping on the vertical direction is getting higher in the high-rise cities [Eicker et al., 2010]. The effect of density on heating, cooling and lighting energy demand of the areas is different and their influences are changing according to climatic conditions.

Characteristics of built environment

Physical properties of buildings and technologies in the building sector have a significant effect on the energy consumption. Insulation properties, windows type and area, the efficiency of technical appliances in buildings such as elevators, escalators, HVAC systems' equipments are profiled the building for evaluation of its energy. Building envelope, this is interface between outdoor environment and indoor conditions, works as a thermal barrier and serves a function in regulating a comfortable indoor temperatures. It plays a crucial role for reducing the need for heating and cooling of building. Moreover the placement of windows and doors, the size and location in the envelope has a significant role on the control of energy losses. Buildings should always be contemplated in the conjunction with their surroundings. In order to manage the use energy of the built environment in a sustainable way and to minimize harmful emissions, the performance of the city scale must be considered. Building energy condition can be characterized with urban pattern, building stock properties and also infrastructure possibilities. In the terms of shading and reflection, lighting and thermal energy loads are influenced by the architectural form of the urban structures and the neighborhood relationship.

Possible renewable energy source applications

Buildings are integrated into networks of overriding technical infrastructures which are water supply, drainage, sewerage, water disposal, electricity system, heating and cooling networks and transportation. The development of more sustainable cities critically depends on a style of urban infrastructure condition that encourages more efficient patterns of resource consumption. District heating or cooling in combination with energy efficiency measures in buildings account for approximately one third of the reduction of emissions [Särnholm et al., 2009]. Therefore, efficient supply system and integration of renewable energy technologies to the network are crucial for sustainable cities. On the other hand renewable energy integration is more meaningful solution at urban scale. Indivual building renewable energy integration is not factual answer for efficiency and feasibility. Renewable energy application on the urban area or district, which is directly connected to the grid so it eliminates transmission loss on the other hand it doesn't use any other land for application, has better energy performance than the individual applications. Solar PV or solar heating system integration on the roof has high potential with easy application. Façade integration has not easy for the underperformance of panels caused by the inequable shading. Wind tirbunes are not easy to implement to the urban district for the reason that it is affected from location of the building, wind direction, heights of surrounding buildings, other roof-top structures and so on.



Building type	One storey house	Row houses	Apartment block
Floor area	10.5mx10.5m	7m x10m	20mx14m
Height	3.5m	7m	10.8 m
Building unit	1 house-	6 houses	1 block-

Figure 1 (a) Energy plus model of one storey house (b) Row houses and (c) Apartment block

METHODOLOGY FOR PARAMETRICAL ANALYSIS

In the urban transformation projects, especially used for residential areas, highrise apartment form is used for restructuring the land in the furtherance of scalling up the recreation and green area opportunity. In order to limit the complexities related with real urban areas, the archetype was defined according to common typologies for transformation projects and this simplified type is used for energy performance simulations. There is not any survey for common building typology in Turkey but the German building stock was explored on the basis of energy demand properties and main residential building typologies defined by Institute for Housing and Environment-Germany (IWU, 2003). According to this research one storey, row houses and apartment blocks take into account for possible former building types of urban transformation area **as shown in Figure1.** According to profesionel point of view similar building forms are commonly used also in Turkey.

The apartment block with 10 storeys is chosen for possible new building form for urban transformation projects in Turkey and Germany. Floor area of the building is 24,4m*24,4m and height of it is 30m. Glazed area on the façade is 35% of the full façade area. Three dimensional urban quarter simulation was done for generic urban form **as shown in Figure 2.** The representative urban quarter constitutes of 9 generic building blocks and the distance between the buildings varies according to site density. The major orientation for the site design is the South. To see the total energy demand of the building, heating and cooling analysis including the annual electricity consumption with daylight responsive control was calculated in the Energyplus simulation program (simulation methodology has been described detailedly in the paper Kesten et al., 2011). Ankara and Stuttgart Energyplus weather data is used for the simulations.

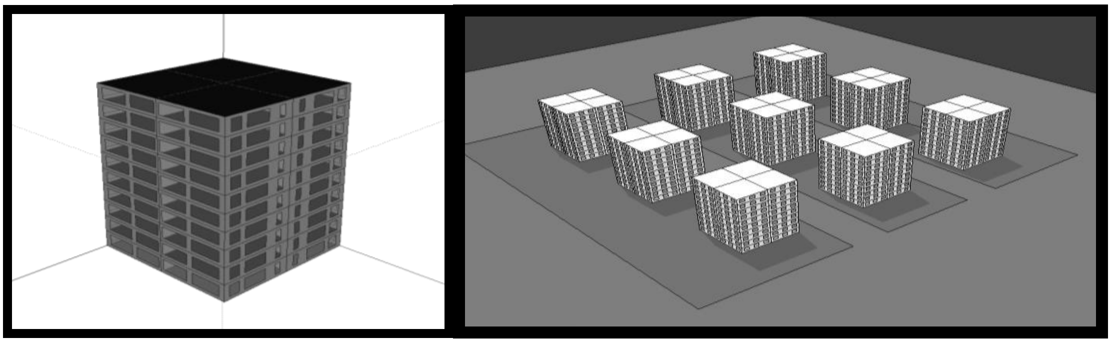


Figure 2 (a) Energy plus model of urban quarter and (b) Energy plus model of urban quarter according site density.

Table 1. U-values (W/m²K) of building envelope according to construction year and building energy standards (LE: Low energy standard, PH: Passive house standard)

Building Component	ANKARA			STUTTGART										
	1984	2000	2008	1948	1968	1978	1983	1994	2000	2007	2009	LE1	LE2	PH
Exterior walls	1.2	0.5	0.5	1.7	1.4	1.03	0.8	0.6	0.5	0.3	0.24	0.23	0.15	0.13
Floor	0.75	0.45	0.45	0.8	0.8	1	0.8	0.6	0.5	0.3	0.24	0.3	0.26	0.19
Roof	0.47	0.3	0.3	0.8	0.8	0.6	0.5	0.3	0.3	0.3	0.24	0.25	0.19	0.15
Windows	2.7	2.6	2.4	5.89	2.72	2.72	2.72	1.93	1.82	1.73	1.3	1.2	0.9	0.8

Occupation of the flats was simulated for an identical family scenario, consisting of 4 family members who are not home during the day except on weekends. The usage time of the appliances was configured according to the statistical data. Every house has television, computer, washing machine, dishwasher, oven, and fridge. The usage was determined as the average time taken from the German household statistic (Gruber and Schlomann., 2005)The EN ISO 13791 was taken as an input for internal gains from occupants. The lighting was defined as 13 W/m^2 and 40% of this is the convective gains. The heating set point was defined as 20°C and cooling set point was defined as 26°C. The heating system was shut down end of April to the end of October and while the cooling was operational for the duration of this time. The properties of building envelope are defined according to national standarts of the countries **as shown in in Table 1.** Simulation has been validated with measured data and it has been described detailedly in the paper Tereci et al., 2010. In the transformation project areas it is assumed that the former buildings in Germany can have been built before 1994 standards. Because of the unplanned development after 1980 in Turkey, the energy values of former buildings can be the worse than this results. But 1984 building standards are taken into account for building envelope which can be the best energy performance case for urban transformation project.

PARAMETRICAL ANALYSIS RESULTS

The heating, cooling, electricity and hot water useful energy demands for possible former building types were simulated without considering the effects of obstructions. These results are **presented in Table 2** and serve as a baseline for comparison. In the cold climatic condition like Stuttgart and Ankara, heating demand especially for residential houses is very important indicator for energy performance of the building.

Heating and cooling demand of the building types in different dense areas were evaluated to get an understanding of the site density effect. **Figure 3 shows** the heating and cooling demand of the former building types located in the centre of an urban block with function of site density densities which were constructed in 1984. Without any shading effect the heating consumption of one storey house is 106.5 kWh/m^2 while depending on the shading of the area the heating consumption can be 12% higher in Ankara climatic condition. The energy demand of apartment block is less by compare with one family house and row houses for both climatic conditions. Site density is affected less in Stuttgart by 8% for one family houses. Especially for cooling loads site density was highly affected in Ankara conditions and coillings loads decrease nearly 50% for all type of buildings.

Table 2. Dynamic simulation results of former reference buildings (construction year 1984) without surrounding obstructions

Reference Buildings	Ankara			Stuttgart		
	Heating	Cooling	Electricity	Heating	Cooling	Electricity
One Family House	106.53	19.44	30	101.53	6.03	33
Row Houses	98.63	15.38	18	94.01	2.82	19
Apartment Block	61.82	19.2	21	62.77	6.87	23

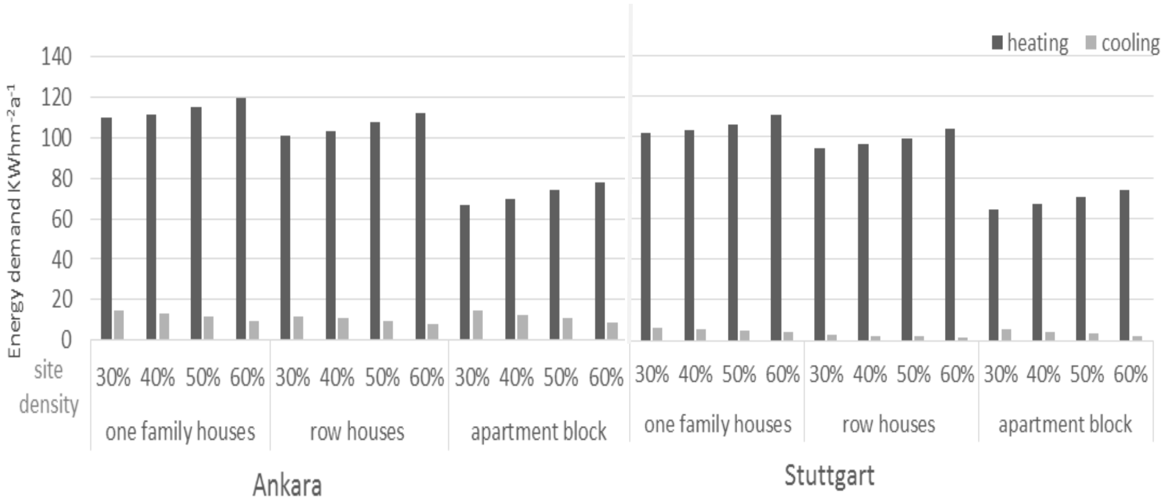

Figure 3 Heating and cooling energy demand of building types with site density

As mentioned before, physical properties of buildings have a significant effect on the energy consumption so the building envelope properties according to energy standards or codes are profiled the building for evaluation of its energy. To understand the effect of energy standards on the buildings, reference buildings are simulated according to different construction years. **Figure 4 presents** the energy demand of eleven versions of apartment block according to different energy standards in Germany since 1948. The passive standard buildings show the heating demand without heat recovery from exhausted ventilation air. Similar trend is observed for one family house and row houses. It is not possible to mention or calculate for Turkey another building envelope properties because of the lack of the energy standards. We can assumed that the buildings which were built before 1984 are in the worse than these conditions and Germany example can have an idea about the effect of thermal properties of envelope. According to results, building standards in 1994 has given a jump for the energy performance of buildings and we can say that for urban transformation project for both countries, the energy performance of the site can be enhance at least 30% for the buildings constructed in the year before 1994.

It is also important to decide for new construction area density for urban transformation project. Therefore ten storeys apartment block which is constructed with current energy standards (Turkey 2008, Germany 2009) was evaluated according to site density and the results are presented **in Figure 5**. The heating consumption of the blocks is 53 kWh/m^2 and cooling demand is 10 kWh/m^2 in Stuttgart. The heating consumption of the blocks is 55 kWh/m^2 and cooling demand is 16 kWh/m^2 in Ankara. Depending on the shading on the site, the heating demand can be 25% higher more and the cooling demand can be 40 % less than the building without shading.

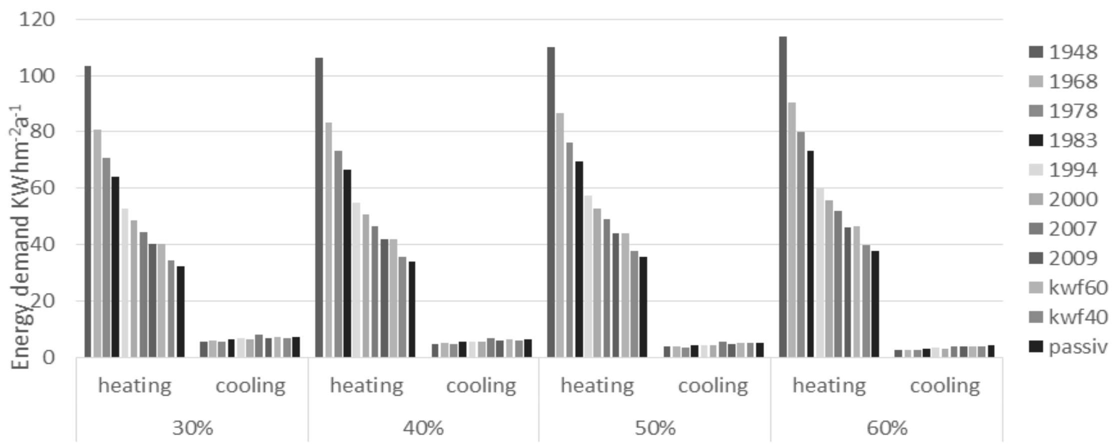

Figure 4 Heating and cooling demands of the ten storey apartment block in Germany with different site densities and envelope properties.

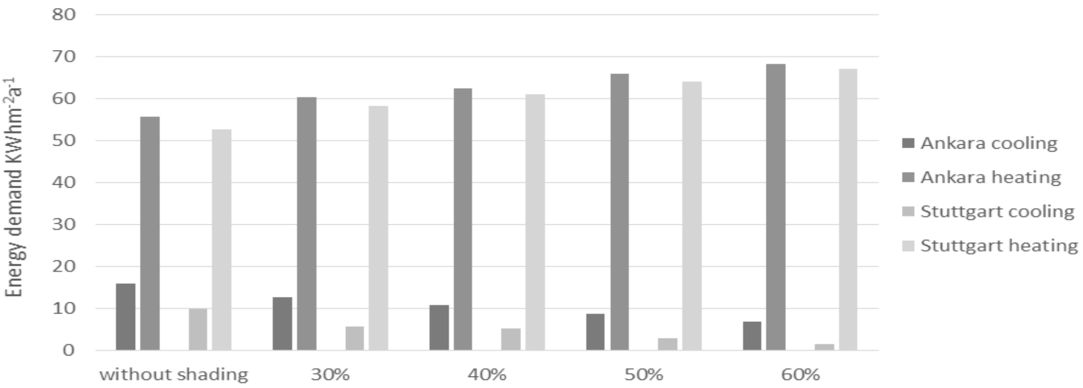

Figure 5 Heating and cooling demands of the ten storey apartment block constructed with current energy standards for Ankara and Stuttgart climatic conditions within different site density.

According to the reference building results, it is not easy to compare the site energy performance. Therefore the site performance of the new and former buildings was evaluated according to the same size urban districts and equal densities. Depending on the building typology chosen, the number of buildings, and therefore the number of housing units and their occupancy will vary. For each building type, the heating and cooling demand of the whole site was simulated at a density of 40% for Stuttgart. These figures are presented **in Table 3.** The average heating demand of ten storeys apartment block for urban transformation project is 60 kWh/m^2 while the average heating demand of one family house is 105 kWh/m^2, row houses' is 98 kWh/m^2 and apartment block with 4 storeys' is 68 kWh/m^2. The urban transformation project can reduce the heating demand up to 43% and it has the similar positive effect on the cooling demand of the site. In Ankara, the average heating demand of ten storeys apartment block for urban transformation project is 58 kWh/m^2 while the average heating demand of one family house is 114 kWh/m^2, row houses' is 105 kWh/m^2 and apartment block with 4 storeys' is 72 kWh/m^2. Reduction on the heating demand by urban transformation project can be 50% and also cooling demand reduction can be seen up to 28%.

In this study, supply scenario an electric heat pump with a COP of 4.0 was chosen as a standard heating system solution, covering 80% of the heat demand, supplemented by a gas condensing burner with 96% efficiency. Cooling was provided by an electric chiller with a COP of 3.0. Also, auxiliary electrical energy for pumping as well as delivery distribution losses of 10% of the heating and cooling demand was added. According to the CO_2 emission factor for natural gas was 0.202 t CO_2/MWh and for electricity 0.539 t CO_2/MWh, per capita CO_2 emissions is calculated. The lowest primary energy demand is ten storey apartment block for urban transformation project but lowest per capita CO_2 is the old apartment blocks.

Table 3. Heating and cooling energy demands of an urban area with 40% site density for different building types

	Number of buildings	**Flats**	**Conditioned floor area/m^2**	**Total heating energy demand/ MWh**	**Total cooling energy demand/ MWh**	**Average primary energy demand (kWh/m2)**	**CO_2 emission /t CO_2**	**CO_2 emission per capita/t CO_2 cap−1**
One family house	88	88	8800	926	61	115.5	176	0.5
Row houses	21	147	20580	2010	596	107.5	378	0.64
Apartment block	31	372	34720	2353	202	87	494	0.33
Apartment block (urban transformation)	14	560	83342	5034	283	79	1291	0.58

In the urban transformation project to add some renewable energy sources to the site is easier than the implemention to former buildings by reason of orientation, construction conditions, shading and etc. It is possible to add some district heating system for both cities and also this system can be combined with cogeneration plant, geothermal heating or central solar heating system in the urban transformation project. These systems can reduce high amount of carbon emissions and burning fossil fuels. For determining the performance of a PV system for the buildings in Ankara and Stuttgart, it was considered that the whole roof area of the buildings would be used for a free standing PV-installation with a tilt angle of 25°. PV-fields with for this example chosen 44 Sunpower SPR-305-WHT panels each, oriented to South. Each PV field was arranged to 4 strings of 11 PV-panels each which are connected to one inverter. The total collector fields and two inverters with a nominal power of 29.34 kW and a power ratio of 1.18. The average energy yield of the system is 34.2 MWh/a for Stuttgart and 48 MWh/a for Ankara. It is possible the produce 25% -35% of the consumed electricity with these installations.

CONCLUSION

The total energy consumption of the cities is crucially influenced by urban design decisions. This study shows that the site density and physical properties of buildings have significant effects on the site energy performance so this kind of evaluation should be made before the design of refurbishment of old settlements area. It is difficult to make the recommendations for all cities since they have unique characteristic and context but according to building standards and density decisions can provide big key for energy management of the cities. There is notable connection between energy demand and the urban site planning. Definitely instantaneous energy demand of the city is highly affected from the energy usage behavior of citizens and operation of the system but statistic mode of energy consumption may give design criteria for energy management decisions. Hovewer in addition to that, the climatic conditions and the population of the area, building typology and the density should be analysed carefully before the urban transformation projects.Detailed dynamic thermal simulations show that 10-20% heating and cooling demand may be saved by an energy aware site planning.

Beside that, renewable energy applications should be integrated in the urban planning process at the beginning in order to maximise the use so the urban transformation projects also have a big potential for integrating the renewable sources. According to this study, there is a big potential to save more than 30% of the energy used with renewable energy integration. This study covers only project site decision for urban transformation projects but better renewable energy integration can be done with district planning.

ABSTRACT

Multifunctional glazing combines various glazing, that have potential to control solar heat gain by changing the window transmittance and low heat loss. In autonomous multifunctional glazing its function will be powered by PV layer attached to the glazing. This glazing obviates the necessity for shading devices to control the glare. Glare control for such a small scale south facing vertical surface multifunctional glazing is discussed.

INTRODUCTION

The building sector consumes 41% energy in USA, 40% EU, and 25% in China. At present, low energy buildings are gaining importance to reduce overall energy demand. A near zero energy building combines two concepts (i) the amount of energy supplied to the building must be small and (ii) that energy should be supplied from the renewable sources. In this context, windows are the most important building envelope component contributing to energy use reduction. Windows offers privacy, visual amenity, comfort and control of light and air. In a direct dynamic relation with outside atmosphere, heat gain and heat loss both ensue through a window. In addition to multiple pane glazing that includes low emittance coatings vacuum glazing, aerogel glazing, building integrated photovoltaic (BIPV) glazing and smart glazing are available. Vacuum and aerogel glazing gives low heat loss from room to environment and reducing heating load demand. BIPV glazing introduces daylight and reduces the artificial lighting load demand. Smart glazing like electrochromic (EC), liquid crystal (LC), suspended particle device (SPD) type control the solar heat gain and reduce the cooling load demand.

Vacuum glazing consist vacuum between two glass panes separated by small pillars to withstand the atmospheric pressure and insulated hermetic edge sealing around the periphery of the two glass sheets. This glazing shows total heat transfer coefficient (*U* value) values between 0.5-0.9 W/m^{2}K (Robinson and Collins 1989; Collins and Robinson 1991; Fang et.al. 2006). Highly insulating vacuum glazing can be achieved using hermetic edge sealing around the periphery of two glass sheets (Collins and Simoko 1998). Addition of transparent low emittance coatings reduces radiative heat transfer between the sheets. Use of two low- e coatings does not reduce the overall heat transfer rate over a single low e coating layer. Using one layer of low e coating also reduces the overall system cost as low e coatings are costly (Fang et.al. 2007). An aerogel is a translucent solid gel that exhibits high thermal insulation, low refractive index, and very low density (Jensen et.al. 2004). This glazing filled with aerogel can achieve a heat loss coefficient less than 0.7W/m^{2}K for 15 mm thick aerogel between two glass panes (Schultz and Jensen, 2008; Schultz et.al. 2005). In BIPV glazing transparent or semitransparent solar cells are placed on the outer facing surface of the glass panes (Miyazaki et.al. 2005, Chow et.al. 2009) which can be used as small scale electricity generation, control solar heat gain and transparency of visible light. In case of electrochromic glazing electrochromic material are placed between two glass panes. An electrochromic material is cell which changes its state from transparent to opaque state by redox reaction in the presence of applied D.C. voltage typically 0 to 5 V (Rosseinsky and Mortimer 2001). The optical properties of EC can be reversed by simple inversion of electrical polarity (Lee et.al. 2003, Granqvist 2012). The speed of this colour change process decrease at higher ambient temperatures. The bleaching to colour process take more time than colour to bleach process. EC material has potential to control transmissivity, absorptivity, reflectivity and emissivity of a glazing (Granqvist et.al.2003; Granqvist 2005). Electrcochromic glazing controls solar heat gain and daylight through a window by blocking the transmission of near infrared (NIR) and visible light (Pennisi et.al. 1999, Granqvist 2000). SPD and LC both work on AC power. Both types become clear when continuous power supply is available and a switched off condition generates an opaque state. Compare to EC glazing LC and SPD switch on response is very fast, within 2 -5ms. Another advantage of these two glazing are they produce equal transparency all over the glazing specifically when the glazing size is larger (more than $1m^2$). EC glazing colouration process takes 5-10 min depending on the size and sometimes the coloration is not uniform. The required electrical power consumption for EC glazing is much lesser than the LC and SPD glazing.

Building occupant prefer to live and work in space with good daylight distribution. Daylight in a building is preferable to saves energy from artificial lighting. Discomfort glare arises from a high or non-uniform luminance distribution with high contrast luminance between source and surroundings. Discomfort happens due to glare sources position, the part of sky seen through and the size of glare sources (Galasiu and Atif 2004; Nazzal 2005). Controlling glare while achieving maximum utilisation of daylight is one the most difficult task for present available window and shading devices. Different shading devices such as external shading, internal shading, and louvers are used to control daylight and glare (Ahmed, 2012; Freewan, 2014). Particularly overhang type shading devices cannot control the glare created from low azimuth angle direct solar radiation. Switchable glazings are capable of reducing this glare.

CONCEPT of MULTIFUCNTIONAL GLAZING

Combining vacuum and EC device gives both low heat loss and switching characteristics to get both effects together (Papaefthimiou et.al. 2006; Fang et.al. 2008). An EC /LC/SPD device needs an external supply to change colour which can be supplied by PV added to the EC (Deb et.al. 2001; Huang et.al. 2012; Huang et.al. 2012). Using EC window and overhang shading in combination (Lee and Tavil 2007) has been studied.

A new multifunctional glazing, shown in figure 1 integrates of all these different existing EC/LC/SPD system, Vacuum/Aerogel, and Photovoltaics (PV). PV generates the power necessary to change the colour of smart material (EC, LC, and SPD). Multifunctional glazing can be solution for new fenestration devices that control the direct solar radiation, improve daylight quality, control daylight and glare. The location of PV layer will have an influential contribution in multifunctional glazing. Different positions of the PV layer will produce different PV outputs that will be used to switch the smart material.

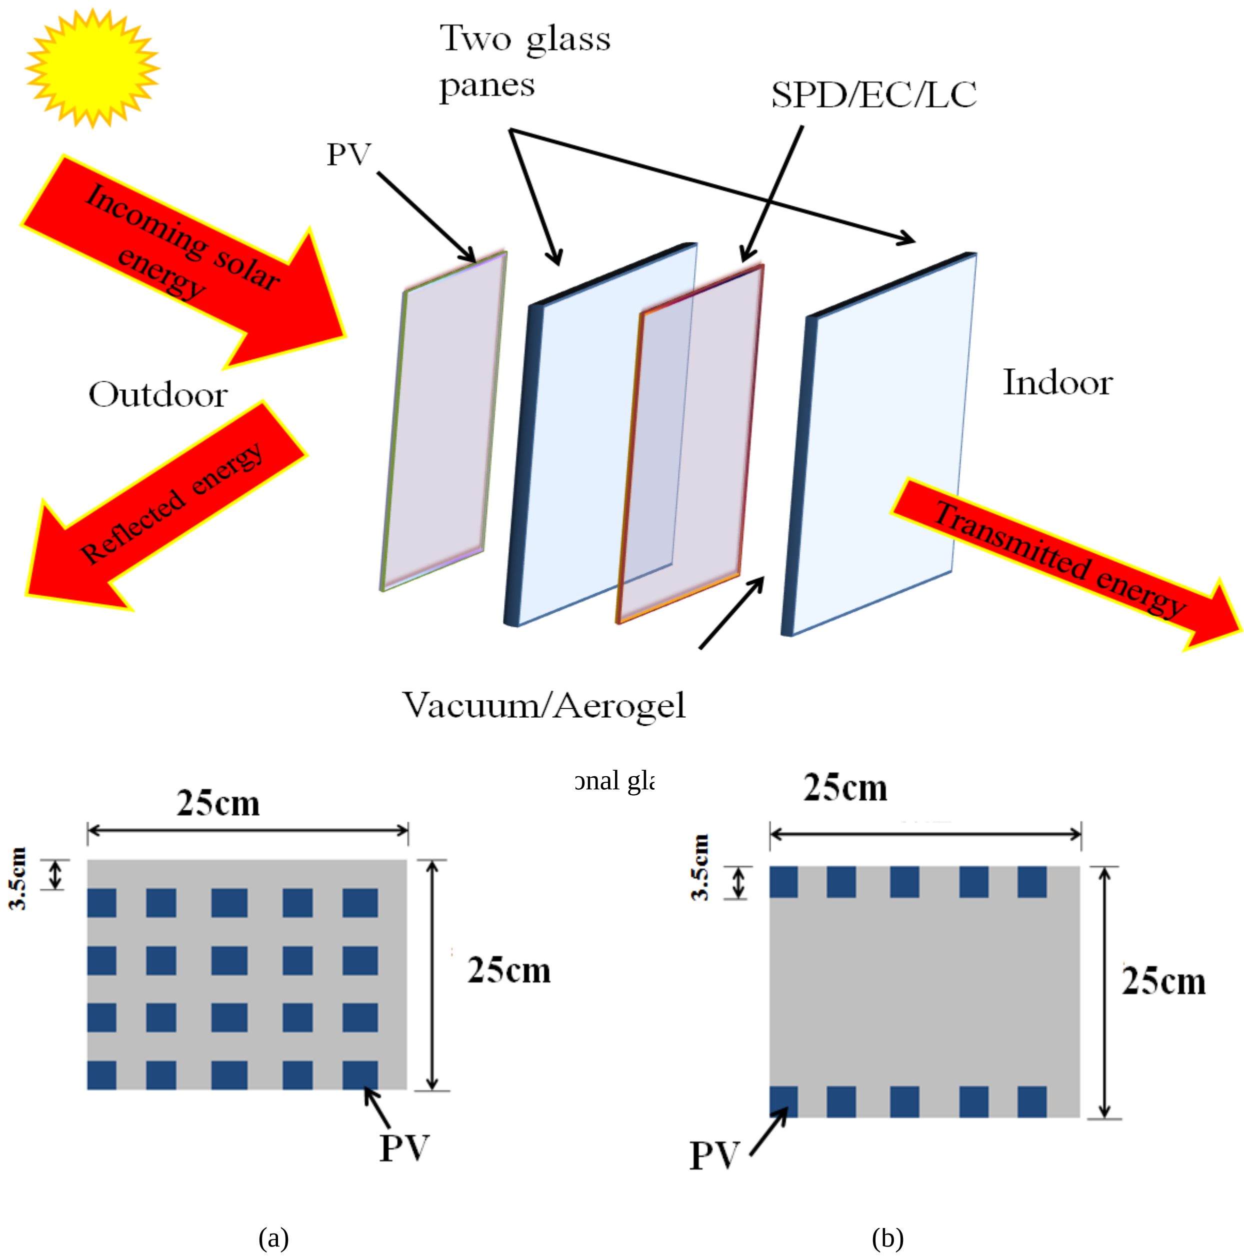

Figure 2 Schematic diagram of semitransparent PV device for multifunctional glazing

Transparency reduces when PV cells are applied to the glass. Organic PV cells have a high transparency compare to inorganic PV cell but durability and efficiency of this type of cells are very lower. Keeping in consideration the cost and durability of the PV cells, silicon PV cells are considered in this study. Figure 2 illustrated two different options of placing PV cells are placed to glazing space to provide a semitransparent glazing. In the figure 2 (a) shows a 20% transparency while figure 2 (b) has 40% transparency. For the multifunctional glazing as shown in figure 1 different transparency level of each and layers are , glass 90%, PV 20% or 40%, EC clear 50% , EC opaque 10%, SPD opaque 5% and clear 58%. Different positions for the PV will result in different PV outputs available for switching the multifunctional window. PV arrays produce maximum power when inclined at the local latitude angle. As windows are usually vertical surfaces most the PV will also be inclined vertically. Depending on the different position of window east west south north the incident solar radiation intensity will also be different. It will be evaluated that how much light and solar radiation will be available for multifunctional glazing and also for different orientation.

Different possible positions of different layers are;

Type 1- Glass, SPD/EC/LC, PV, Vacuum/aerogel, and Glass (here we consider only EC, PV 20% transparent)

Type 2- PV, Glass, EC/LC/SPD, Vacuum/aerogel, and Glass

Type 3- EC/LC/SPD, Glass, PV, Vacuum/aerogel, and Glass

Type 4-PV will be on the frame of glazing, Glass, EC, Vacuum/aerogel, and Glass

This Study considers Type1

METHODOLOGY

Glare index calculation is provided for a 25cm ×25cm multifunctional glazing for a sunny day on 1st of June 2014 in Dublin (53.3478° N, 6.2597° W). The glazing is considered to be on a vertical south façade. Dimension of the room and glazing position and measuring points are shown in figure 3.

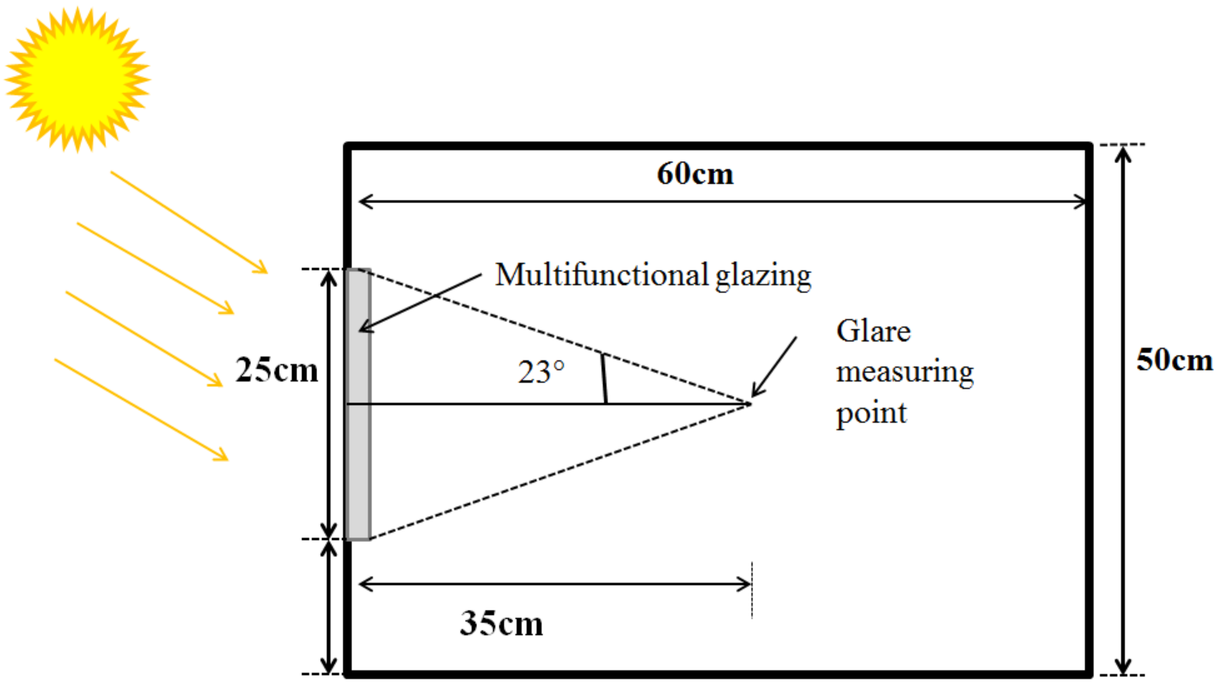

Figure 3 Schematic cross section of a room with multifunctional glazing place on vertical south facade

The available solar radiation I_{g20} inside the room will be

$$I_{g20} = \tau_{g1}\tau_{pv}\tau_{ec}\tau_{vaccum}\tau_{g2}I_{vinci} \tag{1}$$

Solar radiation incident on the vertical surface is calculated from horizontal direct and diffuse solar radiation using equation 2 (Liu and Jordan, 1960) for vertical surfaces orientated, east, west, north and south.

$$I_{vinci} = I_b R_b + I_d R_d + \rho R_r (I_b + I_d) \tag{2}$$

$$R_b = \frac{\cos\theta_i}{\cos\theta_z} \tag{3}$$

$$R_d = \frac{1+\cos\beta}{2} \tag{4}$$

$$R_r = \frac{1-\cos\beta}{2} \tag{5}$$

Angle of incidence are given by

$$\cos\theta_i = \sin\delta\sin\phi\cos\beta - \sin\delta\cos\phi\sin\beta\cos\gamma + \cos\delta\cos\phi\cos\beta\cos\omega + \cos\delta\sin\phi\sin\beta\cos\gamma\cos\omega + \cos\delta\sin\beta\sin\gamma\sin\omega \tag{6}$$

Global illuminance from the global incident solar radiation can be calculated from (Perez, 1990)

$$L = I_{vinci}\left[a_i + b_i W + c_i\cos(Z) + d_i\ln(\Delta)\right] \tag{7}$$

Discomfort glare is represented by glare index (GI) described by (Hopkinson and Collins 1970; Hopkinson and Bradley 1960)

$$GI = 10\log_{10} 0.478\left(\frac{L_s^{1.6}\Omega^{0.8}}{L_{ba} + \left(0.07\omega^{0.5}L_s\right)}\right) \tag{8}$$

The standard glare values are 10 for just perceptible, 16 for just acceptable, 18.5 for borderline between comfort and discomfort 22 for just uncomfortable and 28 for just intolerable.

RESULT & ANALYSIS

Vertical surface global solar radiation is illustrated for different orientation in figure 4. It can be seen that receiving solar radiation on multifunctional glazing is possible during all the day in south facing building. East facing and west facing glazing receive more solar radiation before 12 am and after 12am respectively. For an East facing window in the morning variable transmission control of glazing is essential whereas west facing windows needs control in the afternoon. South facing window needs maintenance of glare and daylitghiting throughout the day

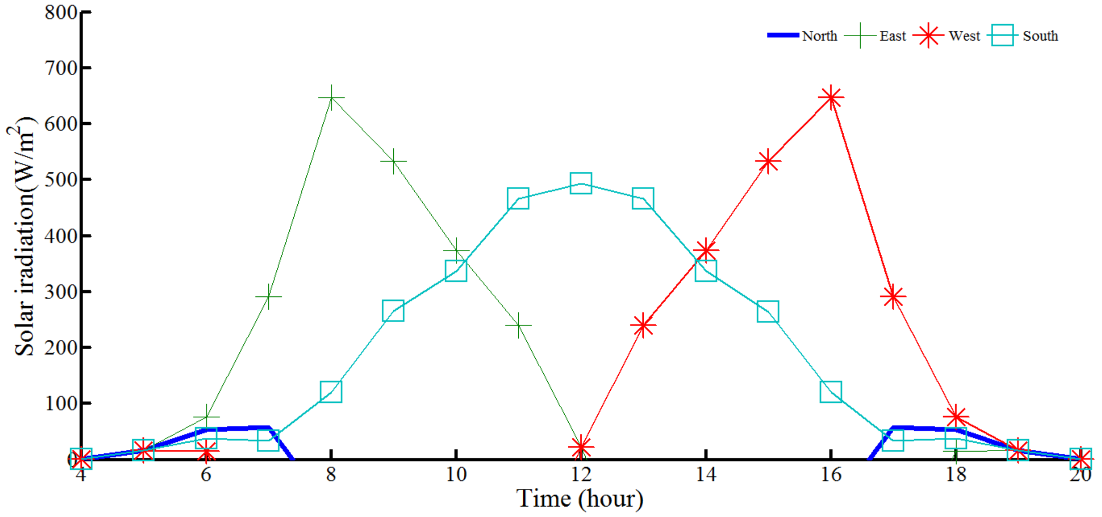

Figure 4 Incident global solar radiations for north east west and south on vertical surface

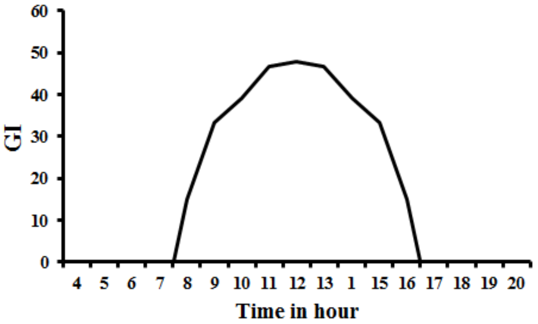
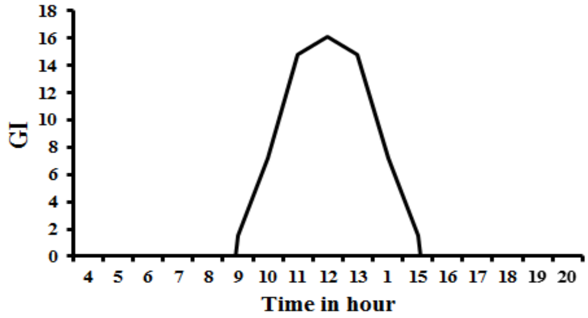
Glare index (GI) for south façade multifunctional glazing for switch off and switched on conditions are shown in figure 5. When EC was switched off its 50% transparency allowed excessive light inside the room. It can be seen that after 8am it crossed the limit of intolerable limit range of 28. At 12am it was nearly 50. This excessive glare can be controlled using the switched on EC with10% transparency rendering the glare acceptable range. At 12 am the maximum glare was 16 just in the acceptable range. In both case the PV transparency was 20%.



(a)



(b)

Figure 5 Glare indices when EC was switched off clear (a) and switched on opaque condition (b)

CONCLUSION

Multifunctional glazing has potential to control heat loss and heat gain and generate electricity to switch a switchable material. This glazing has the potential to control glare. Glare control of a particular room has been found to be provided was theoretically calculated using standard glare index equation. It was found that when EC device was switched off condition the glare was nearly 50 at 12 am which was more than intolerable limit of 28. During the switched on condition the glare was nearly the acceptable range 16 at 12 am.

NOMENCLATURE

I = Incident solar radiation (W/m^2)
τ = Transmittance
L = luminance (lux)
R = conversion factor

Environmental Performance of Adaptive Building Envelope Design: Urban housing in Seoul, Korea

Jeewon Paek, LEED AP BD+C
Architectural Association School of Architecture

ABSTRACT

Since the first construction in 1962, apartment housing represented modernity and quickly became a ubiquitous urban housing typology in the midst of Korea's rapid economic growth. Prominently influenced by the 1930s rational architecture from Europe, the housing site planning for Seoul systematically multiplied into a linear urban pattern of slab typologies. As the city stepped into the 21st century, the old slab typology—criticized for their lack of diversity and low density, adapted a new housing model from North American urban residential schemes—the mega glass tower. Energy consumption of the new tower typology has doubled from the linear slab model due to the increase in glazing ratio, the application of tinted green double glazing in replacement of clear double glazing, and the irregular orientation of the floor plans. This research analyzes the environmental performance of the new tower typology in comparison to the previous slab typology with the objective to improve the quality of future urban housing design and planning in Seoul.

INTRODUCTION

1930s rational architecture from Europe prominently influenced the housing site planning for Seoul, which systematically multiplied in a linear urban pattern. Consequently, typical urban housing layout in Seoul has the characteristics of expanding horizontally or orthogonally in clusters. These forms of clusters follow a linear, single orientation, slab configuration which conceptually provides a level of equality in housing that is in line with early ideas of modernity in the realm of architecture (Kang, 2004, p. 144-146). From a practical perspective, each unit could receive an equal amount of daylight, cross ventilation, and views outward within this system. This idea of equality, despite its formation of unity in the residential sector, simultaneously erased local identities of neighborhoods to the point where eventually every development appeared the same as the other throughout the entirety of the city.

Figure 1 1960s to 1990s Old slab typology apartment housing in Seoul, Korea.

Quite recently this linear apartment development strategy and residential culture have come under critical scrutiny. As the city stepped into the 21st century, the slab typology has been criticized for their lack of life quality, diversity, and dynamic urbanism. The old slab typology building can no longer provide the high density required by the city and create a healthy urban living environment. Developments from the 1960s to 70s remain in poor condition until the point of demolition (Kang, 2004, p. 143). As a reaction, from the demand for housing supply and its heavy reliance on the market, the scale of developments has increased to the mega glass tower. This residential tower typology of higher density is a model adapted from contemporary North American urban residential schemes. The tower simply as a typology has decreased the quality of residential living furthermore, in terms of creating a variety of housing clusters on a block and integrating with the urban built environment and community. Thus, a successful housing model does not exist yet in the city.

Figure 2 New tower typology highrise housing preconstruction sales in Seoul, Korea.

This research determines to analyze the environmental performance of the new tower typology with the objective to improve its quality in terms of architectural design and energy consumption through the building's envelope. Further examination of the relationship between the building envelope and environmental impact of the urban layout provides insight for sustainable housing developments in Seoul.

BASE CASE STUDY: SLAB TYPOLOGY ENERGY PERFORMANCE

The typical slab housing typology constructed from 1960s to 1990s, were built to the height of 8-10 story as multifamily mid-rises with one or two vertical circulation cores servicing all the residents of the building. This typology allowed for each unit to have a double orientation towards north and south, guaranteeing a sufficient amount of daylight, cross ventilation, and solar gains.

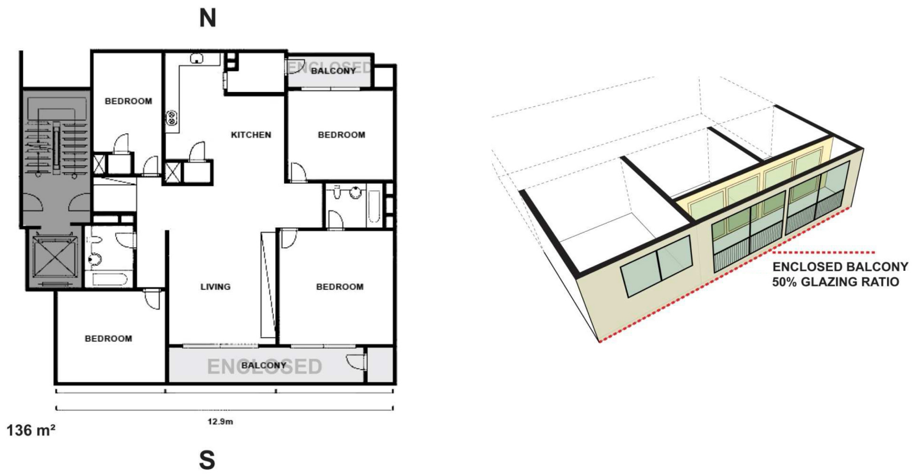

Figure 3 Floor plan of the old housing type used in the base case study and diagrammatic depiction of the enclosed balcony.

An old slab typology flat of 136m² was studied as a base case. It was constructed in the early 1980s and had been planned for demolition in the near future by the developer into new residential buildings. When examining a typical floor plan from the slab typology, two important characteristics of the layout are the open kitchen to living room floorplan and the enclosed balcony spaces to the south and north exposures. The open plan layout is crucial for effective natural cross ventilation during the humid months of July and August. The distribution of internal gains from the kitchen is an insignificant amount according to the occupant, but still a diminutive contribution to the internal temperatures as an auxiliary source of heat.

The enclosed balcony spaces function as buffer zones that control heat loss during the winter and also have the purpose of solar protection in the summer season as overhangs or cantilevers. The balcony of the slab typology is typically a glazed area of 50% to the façade area, detailed with two sliding window apertures that open 50% horizontally. The exposed south vertical surface of this flat in the base case study also has a 50% glazing ratio to the façade. Clear double glazing is used on the apertures to the exterior as well as to the glazed interior sliding partitions that divide the balcony from the interior living room space. The advantages of controlling heat loss as a buffer space, and storing the captured solar gains to the flat is a key factor found in the floor plans of the old slab typology.

Climate Condition of Seoul

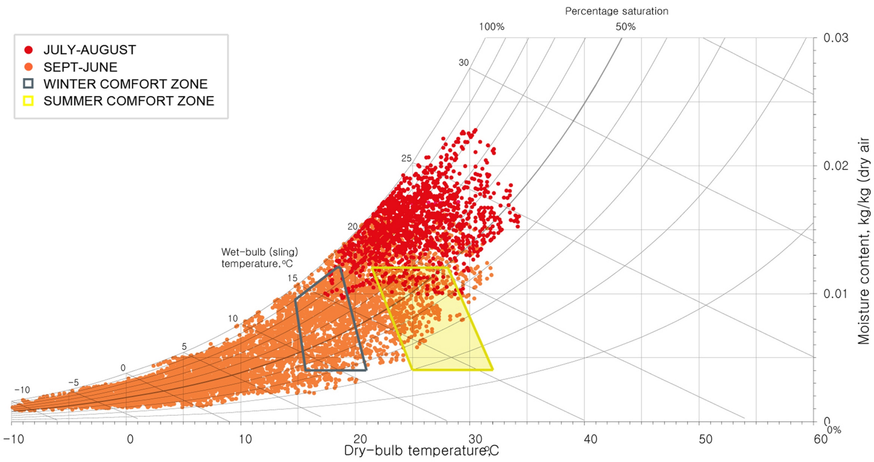

Figure 4 Psychrometric chart defining the summer and winter comfort zones (Szokolay, 2007).

The comfort band calculated from the equation, Tn = 17.8 + 0.31 x To, defines the summer comfort band range between 23 °C and 28 °C. The winter comfort band ranges from 17.5 °C to 20.5 °C. From the psychrometric chart, the red points plot the months of July and August. The relative humidity levels are high throughout the entire year but only falls outside the boundaries of comfort when the external temperature starts rising in the summer months of July and August. The yellow boundary defining the summer comfort zone shows that for the majority of July and August are outside comfort limitations. Consequently, cooling load consumption is also the highest during this period of discomfort due to this relative humidity level.

BASE CASE STUDY: TOWER TYPOLOGY ENERGY PERFORMANCE

Urban housing in Seoul has changed drastically since 2000 in terms of typology, construction, design and not absolutely for the better. The market demanded for housing with significantly higher density as the city became over populated. As a consequence, office-tower type urban residential models found common in North American cities (i.e. New York City, Los Angeles, and Chicago) were adapted into the residential sectors of Seoul. These towers satisfied the market's new density demand and provided diversity in the design of the floor plans (in comparison to the simple slab floor plates), in its irregularity and asymmetry. Each unit found more variety in the layout of the interior spaces and orientation towards the city. But these deeper tower plans have appeared to create new problematic environmental issues. The new tower typology unit which is analyzed closely as a case study is a corner unit of 132m² exposed to both south east and south west. Most of the units within the towers have lost the benefits of natural cross ventilation and north-south orientation of the old slab model. Externally the tower typology has not been able to address its contribution to the urban fabric of the city in providing an improved open space. In fact, the quality of the open space is in greater threat of diminishing due to the height and higher obstruction angles created by these mega towers.

Urban living in a dense city such as Seoul is a constant fight for more space. Due to the desire for maximizing floor sq meters for liveable space, the previous enclosed balconies have been erased for maximum floor sq meter and consequently the envelope has become a 100% fully glazed façade. From the post occupancy evaluation with the family, most discomfort was expressed during the summer months for overheating, weak natural ventilation, and high bills for cooling. In the tower typology base case, poor operable aperture on the glass façade with a small area of merely 0.84m² which tilts outward with a maximum angle of 30°, is a hindrance to the performance of natural ventilation.

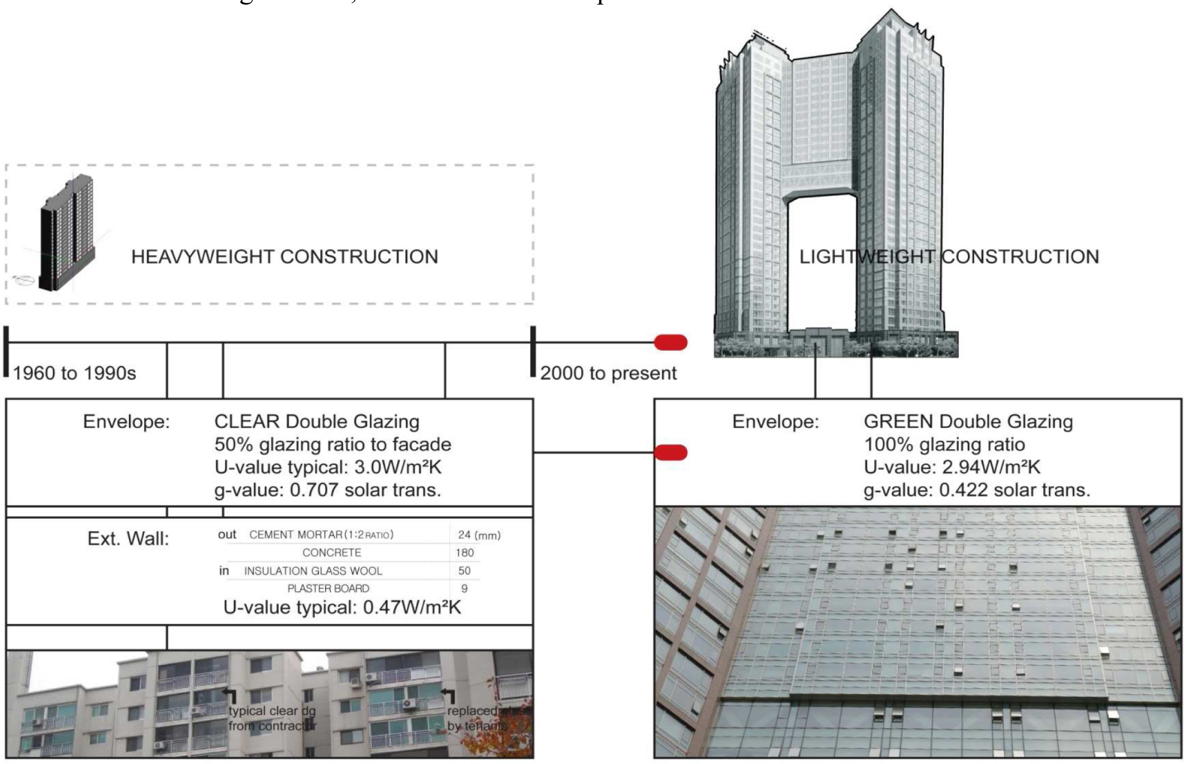

Figure 5 Construction standard comparisons between base cases of the old slab typology and the new tower typology (Jang, 2002).

Glazing Type and Thermal Performance

An essential difference between the two typologies is found in the envelope of the building. In terms of construction, the heavyweight construction of the old slab typology has transformed into lightweight construction in the new tower typology. The external wall of the slab typology had a typical U-value of 0.47W/m²K—concrete load bearing wall construction with insulation placed on the inner side of the wall. In the old slab model, the envelope of the building had a 50% glazing ratio to the façade. This ratio increased nearly to 100% in the new towers. Clear double glazing with a standard U-value of 3.0W/m²K and solar transmittance g-value of 0.707 has been replaced with tinted (commonly green tint) double glazing with a solar transmittance g-value of 0.422. The tinted glass has become a conventional strategy by contractors for urban housing to accommodate the increased glazing area and reduce overheating. In the new tower typology base case, poor operable aperture on the glass façade with a small area of merely 0.84m² which tilts outward with a maximum angle of 30°, is also a hindrance to the performance of natural ventilation.

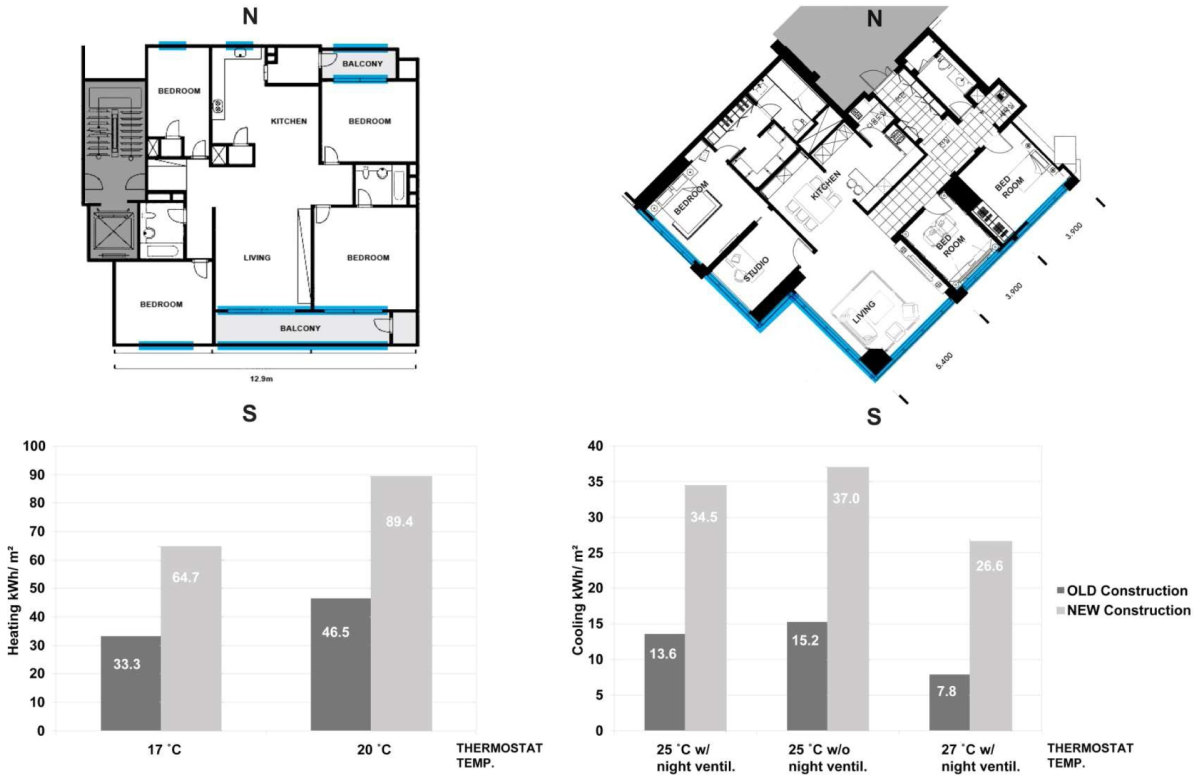

Figure 6 TAS simulation results show that the new tower typology unit has multiplied in annual heating and cooling consumption by approximately 50% in comparison to the old slab model. Previous research data collected from various organizations such as, the Korean Solar Energy Society, Seoul National University of Technology, and Korea Institute of Energy Research Department showed thermostat temperatures set at 20°C for winter heating simulations and 25°C for summer cooling. Both units are 136m² and 132m² in floor area, similar in the layout of the interior spaces, and with the same occupancy.

Impact of Obstruction by Urban Layout and Energy

An important issue to deal with is the urban planning of the new tower typology. What environment or context should the tower be in? A repetitive distribution motivated by careless market driven developments will lead to the identical banality created by the old slab typology. Urban planners and city authorities must have a higher awareness to prohibit monotonous, simply cost-saving development. The sheer height of the new typology creates a greater challenge in terms of integrating with the urban fabric at the ground level. Environmentally, the longer overshadowing of neighbour buildings and the open outdoor spaces must be taken cautiously into consideration during the early urban planning stages.

Figure 7 Aerial photo depicting the urban layout of the old slab vs. the new tower typology. The typical urban canyon of the old slab typology in Seoul was a 1 to 1 ratio of height to width.

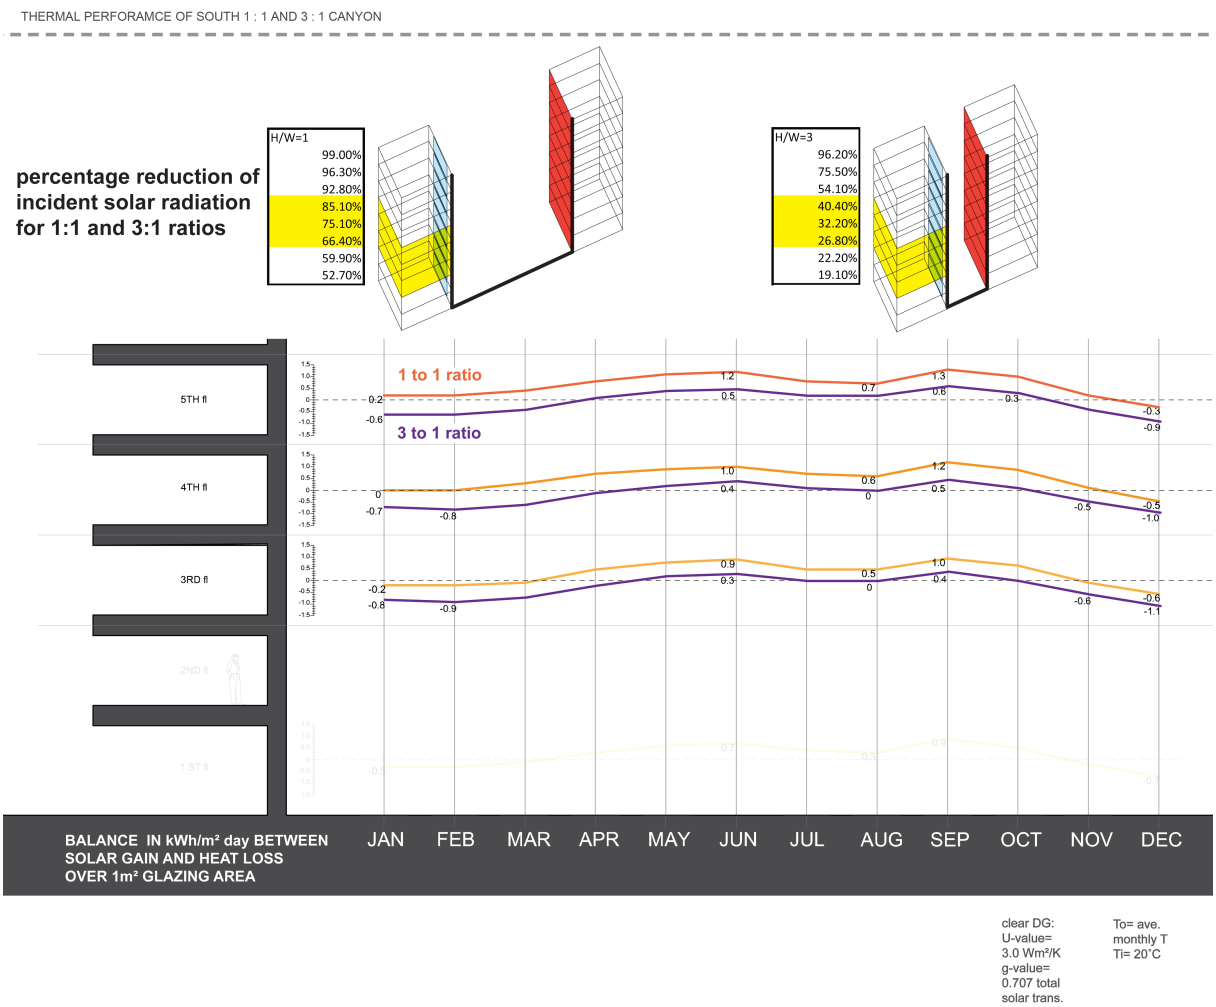

Figure 8 The thermal performance of a 1m² clear double glass glazed area for the two urban canyon ratios-- 1 to 1 and 3 to 1 ratio, maintains a parallel pattern to each other for the entire 12 months.

Three mid floor levels are studied to understand impact of obstruction angles. The balance in kWh/m²day calculates the difference between amount of solar gain and amount of heat loss over the area of a 1m² glazed vertical surface. At the 3 to 1 ratio urban canyon, the percentage reduction of annual incident solar radiation is already less than half of the available amount falling on the south vertical surface of a 1 to 1 ratio canyon. Corresponding to the different percentage reduction in the annual incident solar radiation, the thermal performance of glazing also shows a similar 50% to 60% difference between the two urban canyons. To take a specific example, in Figure 8, the 5th level floor which has a positive balance of solar gain than heat loss until the month of December in the 1 to1 ratio canyon; at the 3 to 1 ratio canyon it shows for almost half of the year, there is greater heat loss than solar gain through the glazed area.

Figure 9 The chart studies the thermal performance of different types of glass. Four types are studied: clear double glazing (U-value: 3.0 Wm²/K, solar transmittance g-value: 0.707), double glazing with low-e (U-value: 1.8 Wm²/K, solar transmittance g-value: 0.616), triple glazing (U-value: 1.2 Wm²/K, solar transmittance g-value: 0.64), and green tinted double glazing (U-value: 2.94 Wm²/K, solar transmittance g-value: 0.422).

The conclusion from this study is that, the three glazing types: clear double glazing, double glazing with low-e, and triple glazing, because of it proximity in solar transmittance g-values, perform similarly in the summer climate of Seoul. But for the cold winter months of November through February, the balance between solar gain and heat loss starts to vary according to their different U-values. In terms of thermal performance for the lowest level floors at the ground, double glazing with low-e appears as a sufficient application for glazing choice to minimize heat loss.

The green tinted double glazing which has been applied to new urban housing construction in Seoul as a substitute or response to higher glazing ratios in the façade performs the worst in the winter season. Due to its lower solar transmittance g-value, the summer performance is stronger than the other options but it is at the cost of an extremely poor winter performance.

CONCLUSION

With an informed building envelope that responds to the climate in Seoul, the performance of the new tower typology is significantly improved. In terms of general strategies for energy saving for the new tower residential typology in Seoul, the most effective measures were found first in replacing the green tinted double glazing(0.422 g-value solar transmittance) with double glazing with low-e. Though the annual cooling consumption increases by 41% with the higher solar transmittance (0.707 g-value) of the double glazing with low-e, the more problematic energy consumption is in heating and this increased cooling amount is reduced again with the application of external shading. The second general strategy is to improve the U-value of the external walls from the standard of 0.47 Wm²/K to 0.28 Wm²/K. The improvement in the U-value of the external wall improves heating consumption by 11%. In addition the application of insulated night shutters and external shading devices to the façade of the new residential tower typology is crucial as an architectural solution in response to the demand for higher glazing ratios. Night shutters with 20mm of insulation with a 0.026 conductivity, can save 30% of heating consumption. The same device which is used as an external shading device can reduce 55.2% of cooling consumption. External shading devices dissipate any absorbed solar energy to the outside air and therefore play a key element for passive cooling. Internal blinds were the least effective in terms of solar control in comparison to external blinds.

To push energy savings to extremely lower values, selective use of the enclosed balcony is necessary in the interior. The final strategy can theoretically achieve values as low as 12.5 kWh/m² for annual heating consumption and 8.1 kWh/m² for annual cooling consumption.

Establishing Energy Efficient Building Codes in Developing Nations:

An analysis of window characteristics suited to hot-dry climates through a study of the residential byelaws of Lahore, Pakistan.

Maryam Siddiq, MArch
Glasgow School of Art

ABSTRACT

Evidence that windows are responsible for most heat gain through solar radiation into a building underlines the importance of climatically sensitive window design. Many of the recent building practices in the developing world are dismissive of the more environmentally appropriate traditional building forms, adopting instead, an urban form that is neither environmentally sensitive nor sustainable. Such practices demonstrate a lack of understanding between the thermal performance of windows in relation to the urban geometry, yet are in most instances legitimized by inadequate regional building codes. A case in point is that of Lahore Pakistan, where despite a predominantly hot-dry climate there is no mention of suitable apertures within the building code, this situation is exacerbated in residential areas by the byelaw requiring a mere 1.7m distance between the building unit and boundary wall on two sides of the building. Taking Lahore as a prototypical developing world city, this paper addresses the specific spatial arrangements created through the existing building codes and focuses on controlling solar gains through an analysis of the window characteristics that are most suited to the climatic and urban environment. The discrepancy in building codes is investigated through software simulations that evaluate real housing clusters with particular focus on the obstructed facade (by boundary wall or adjacent building) for which suitable window characteristics that balance seasonal natural light and thermal gains are determined. A further set of simulations addresses the effect of modifications in the byelaws regarding the distance of obstruction and the consequent adjustments necessary to window characteristics. The results of these simulations provide the knowledge-base for a critique of the environmental sensitivity and suitability of the existing byelaws, and propose modifications that would optimize both climatically appropriate window design and land use within the urban environment of Lahore.

INTRODUCTION

The twentieth century technologies and universally available materials have greatly facilitated the trend towards homogeneity of the urban built form across the globe. This trend is popular in all aspects of urban built form but is particularly obvious in the form of public and commercial buildings in most city centers the world over.

Traditional building design was perfected over a long period of time, with the construction practices, architectural vocabulary and urban form of a region being sensitive to the climatic conditions and cultural requirements of that region. The result was an urban-scape unique to the place and the people, with the building envelope maintaining comfortable indoor conditions.

However the influence of new materials and technologies has resulted in a drastic shift in the built form which in most instances is far removed from tradition and also the goal of maintaining comfortable indoor conditions. While these changes to the urban form have been somewhat conscientiously undertaken in First World Countries in that desirable indoor conditions remain within achievable limits, the situation within developing countries, particularly those with hot climatic regions, leaves a lot to be desired. The *modern urban form* in such parts of the world and the accompanying lifestyle is largely reliant on mechanical methods of air conditioning to maintain comfort which is an unsustainable and expensive option. This situation is exacerbated by the unquestioned adoption of design standards that have been developed in colder parts of the world and are geared to satisfying comfort and energy use in developed nations. The extent of this practice can be gauged by the situation in much of South Asia where the comfort standards laid out in ASHRAE guidelines have been incorporated within the national building standards and are legislatively enforced. The irrationality of such practice is reinforced in recognizing that even within regions of the world that are similar in their climatic environment, variations in the comfort parameters will exist due to the differences within the culture and lifestyle choices of the people of the various regions.

The formulation of a robust workable code is rooted in an understanding of the environmental efficiency and behavior of different building types within the particular climatic and cultural environment of that region. Such understanding is typically based upon empirical data, however it appears that not all building types have been given due attention; the urban residential form has been largely ignored in this regard, with the major focus of such research being the traditional building (Oktay, 2002) while the study of modern buildings has remained almost exclusively within the realm of office buildings. It is therefore an imbalanced understanding of thermal comfort and occupant behavior that has been created and on which we continue to base our requirements of comfort.

A robust building code implemented within a well-designed regional energy policy would go a long way toward improving this situation by ensuring the design and construction of all buildings (irrespective of purpose) results in the internal environment being as close to comfort parameters as possible. Comfortable conditions could then be achieved through passive control or low energy measures and if artificial air conditioning were still required, the reduced temperature differential between the desired and existing would result in a significant reduction in energy costs.

In the absence of an accurate database of regionally appropriate comfort parameters the environmental efficiency of the buildings cannot be gauged nor a solid measure of the success of building standards formulated. At the very least, existing inappropriate guidelines can be modified in order to adapt them to the local climatic conditions. Focusing on the hot-dry South Asian scenario, the primary *design flaws* in the existing standards that render it inapplicable are:

The glazing ratio: The design guidelines for window size and placement were developed in climates that design for daylight: providing adequate natural light in to the building. These recommendations were based on the window area to wall area of the room and vary for different climatic zones; the consensus however is that the optimal glazing ratios lies between 25% and 40% providing adequate light while not incurring undesirable thermal gains and avoiding disability or discomfort glare (Muneer et al, 2000, Baker et al, 2000). In a hot climate, however, there is ample sunlight and providing natural light into the building is not of concern. Rather, the glazed surface area needs to be managed in order to control the solar gains in the building.

Rate of air change: Traditionally based on standards developed for maintaining desirable internal conditions in a conditioned environment, the rate of air change is not applicable to naturally ventilated buildings in hot climates where the speed of air takes precedence over rate of air exchange purely for the cooling effect of air movement.

The following addendum to the standard requirement of air changes is seen as:

Wind speed: The cooling effect of wind speeds between 0.5m/s and 3m/s has been documented however speeds above 1.5m/s are not advised because of the nuisance factor created through the disturbance of paper etc. (Baker, 2000). The cooling effect of re-circulated air through the use of mechanical fans is utilised in most hot climatic regions the world over. This reliance on fan generated wind speed to counteract the effect of increased temperature has been documented to ‘occurs [sic] at temperatures of around 26^{o}C’ (Nicol et al, 2014 p.128). The consequent reduced temperature is known as the *Effective Temperature*. The cooling effect produced is significant with a wind speed of 1m/s causing a 3^{o}C reduction in effective temperature at 30^{o}C (Baker, 2000), and 4^{o}C at 40^{o}C (Nicol, 1994).

It is surmised that recirculation of indoor air in hot climates would prove a beneficial low energy measure and should be accommodated within building standards and guidelines particularly in such regions where such practice is established.

Thermal Comfort in a hot-dry environmnet

The rigidity of comfort parameters determined through climate chamber experiments does not reflect the seasonal variations within conventional comfort ranges wherein occupants adapt to the environment and accept significant deviations in their surroundings. This behavior has been utilized in the development of the adaptive model for achieving comfort and recently this approach has been validated by several international standards such as ASHRAE 55-2004 and EN15251 through the recognition that indoor comfort temperatures are dependent on changing outdoor conditions (Nicol et al, 2014).

One such representation of the relationship between indoor comfort temperature and outdoor temperature is the 1978 formula developed by Humphreys:

$$T_c = 12.1 + 0.53T_o \qquad (1)$$

Where T_c is indoor comfort temperature and T_o is outdoor temperature.

This formula has been found to be 95% accurate in predicting comfort temperatures during summer months for occupants in environmentally controlled buildings in the South Asian country of Pakistan (Nicol et al, 1995). It is assumed that the range of validity of this formula will have an upper limit of 47^{o}C, (the average high temperature of Multan, one of the 5 cities in the study and with the highest average temperatures of the sampled cities).

It is to be noted that this equation does not take into consideration the cooling effect of wind speed. The use of ceiling fans is standard adaptive behaviour in such climatic conditions and the Oxford Brookes report specifically mentions the cooling effect of ‘about 2^{o}C for average air movement’ in Multan with ‘an approx 4^{o}C shift between still air and 1m/s’ (Nicol, 1994, p23). A modification of Humphreys’ formula is thus undertaken to incorporate a conservative 2^{o}C reduction in temperature due to the effect of re-circulated air movement, giving the relationship for *Effective Comfort Temperature* ($T_{ce.}$):

$$T_{ce} = 10.1 + 0.53T_o \qquad (2)$$

LAHORE, A CASE IN POINT

The case study undertaken is the city of Lahore in Pakistan, a typical developing world city which is prone to the issues of conformity to developed world trends in urban form and lifestyle. Located at 31.34^{o}N and 71.20^{o}E, Lahore experiences severe hot-dry summer with a mean average temperature of over 35^{o}C for five months of the year and remaining over 30^{o}C for a further two months (Weatherspark, 2013). With peak summer temperatures of over 45^{o}C, the control of solar gain was the central design consideration in indigenous architecture. The modern urban form however has abandoned the dictates of tradition, with thinner walls (standard construction of 9” load-bearing brick masonry), lower thinner flat roofs, and significantly larger glazed apertures – where previously apertures were small and were protected from the sun’s glare by either external open-able shutters or fixed marble/wood jalli.

The situation in Lahore epitomises the unsustainable condition of the urban-scape of many parts of the developing world with the existing energy regulations based on inadequate research and the local building codes largely ignoring the issue of thermal performance of residential structures. Lahore falls within the same climatic region as Multan, and as such the predictive values of Equations 1 and 2 in the preceding section are applicable. In Lahore where the mean maximum summer temperature is 40.4^{o}C, indoor comfortable conditions would be at 33.7°C, or at 35.7°C where the environment is supplemented with fan-generated re-circulated air.

The Building Code

Much of the residential development within the city falls under the jurisdiction of two major and several minor building control agencies all of which conform to national recommendations. Through this, residential structures within Lahore are regulated within the same byelaws and guidelines irrespective of their location. Universally the building codes specify mandatory clear areas on the periphery of plots –the depth of which is dependent on the dimensions of the plot, residential units are restricted to two storeys in height with a maximum height of 8m and with the upper storey limited to 75% of the floor area of the ground.

The cultural trend, supported by the high land prices is to construct over the entire area permitted by the building codes. This trend combined with the uniformity of plot sizes, a rectilinear *industry standard* road network, and building code dictated volumetric conformity produces a high density low-rise urban form which has remarkable similarity with respect to open spaces between buildings and solar shading by adjacent buildings.

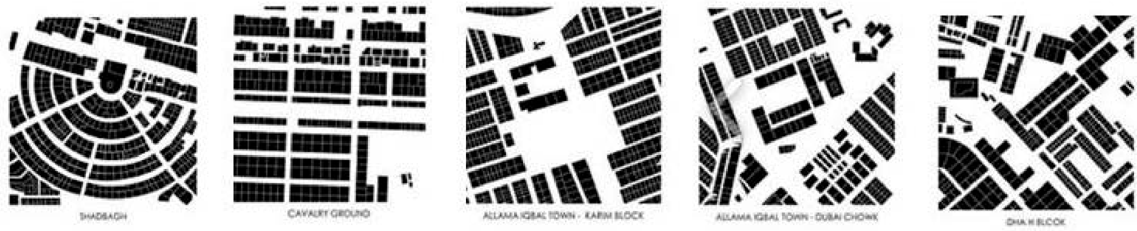

Figure 1 Nolli plans of a sample of residential colonies in Lahore. Density of form and compact nature of planning is clearly visible. (OCCO, 2009)

The primary focus of this study is the largest development authority of Pakistan, The Defence Housing Authority (DHA) within which the development typifies the urban geometry of the city both in density and building form. An initial survey of the sample residential units within the DHA confirmed the translation of the building guidelines is taken literally: in most instances the minimal distance required towards the sides (and the rear of all but the largest plot size) of the residential unit, a mere *passageway* of 1.7m (including boundary wall width) is maintained. Further to this, as the bye-laws limit the height of the boundary wall to 2.13 metres, the facades on at least two sides of all residential units are affected by an obstruction in the form of the boundary wall and close proximity of the neighbouring building.

Table 1. Existing Byelaws for Residential Plots, DHA, Lahore Pakistan (DHA, 2002)

Area (m^2)	Area (sq.yd)	Dimensions (m)	Front (m)	Rear (m)	Side (m)	Side (m)
836	1000	22.86x36.58	6.32	2.55	1.7	1.7
836	1000	30.48x27.43	6.32	2.55	1.7	1.7
418.3	500	15.24x27.43	4.8	1.7	1.7	1.7
211.27	250	10.67x19.80	3.28	1.7	1.7	1.7

METHODOLOGY: ANALYSIS OF THE EXISTING BUILDING

The current building codes in Lahore have not been designed with a view to develop an environmentally sensitive and sustainable urban form. However an analysis of the buildings created through conformation to the building code will determine a base line of environmental suitability of the code. In order to determine the primary source of uncomfortable indoor conditions, the dissection of the urban form into its basic parts: the building and the urban geometry formed of neighbouring buildings is undertaken.

A random selection of existing residential buildings within the DHA area – providing at least 5 from each plot type, yielded a set of building plans that were then analysed, the significantly atypical disregarded and from the remaining sample pool, a ‘typical’ residential unit selected.

Preference was given to the 500 sq.yd. (418.3m^2) buildings as these are representative of approximately 70% of the residential building size in DHA. Furthermore the byelaws applied to this plot size require the minimum distances of 1.7m from the boundary wall on three sides resulting in greater applicability of any analysis.

Figure 2 (a) Building footprint of randomly selected existing residential buildings within DHA limits. Prototypical residential unit used for modelling purposes highlighted. (b) 3D model and floor plans of selected residential building.

The typical residential unit selected above is simulated with the EDSL’s (Environmental Design Solutions Ltd) software Thermo Analysis Simulation (TAS). For the purpose of this analysis, the building is modelled in peak summer conditions for one day (day 180/360) with the number of preconditioned days set to 15 (this equates to the building experiencing the environment for 15 days and analysed on day 16, providing a realistic representation of the environmental sensitivity of typical buildings). The building is simulated as unoccupied and without internal gains so as to provide an unadulterated measure of the effect of the outdoor environmental conditions. The internal partitions are taken to be unopened. The building envelope is true to popular construction materials and the apertures are single-glazed with a U-value of 5.7 which reflects occupant preferences based on empirical sales figures: 65% of occupants opt for single-glazed while 35% opt for double glazed. The primary focus of the study is the ground floor level of the building so as to minimise the effect of thermal gains through the roof.

The contribution of the urban geometry:

The typical residential building was modelled under various exogenous influences that together make up the urban geometry of the area. The building was simulated with each parameter in isolation and also incrementally to determine the effect of the urban geometry as a whole, thereby determining which areas need addressing with regard to environmental sensitivity.

These parameters are: the influence of the boundary wall at 1.7m, the neighbouring residence at 3.4m, and the overall effect of the urban-scape (a residential block of 6 houses, with the central one analysed). These simulations showed an expected increase in the internal temperature of the building unit due the introduction of the boundary wall, however there was no significant change to the internal conditions due to changes in distance of wall from the building edge. Furthermore it was found the close proximity of the neighbouring residence had a positive effect on the indoor climate possibly through the shading factor of building. Overall it has been determined that the effect of the urban micro-climate is an increase in the indoor temperature of the residence, by a maximum of 0.6°C.

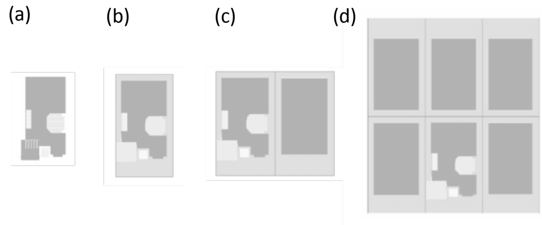

Figure 3 Representative plans of the typical residential building as simulated: (a) building in isolation, (b) with 2.13m high boundary wall at 1.7m, (c) with boundary wall and adjacent building at 3.4m., (d) within a typical block of residential units.

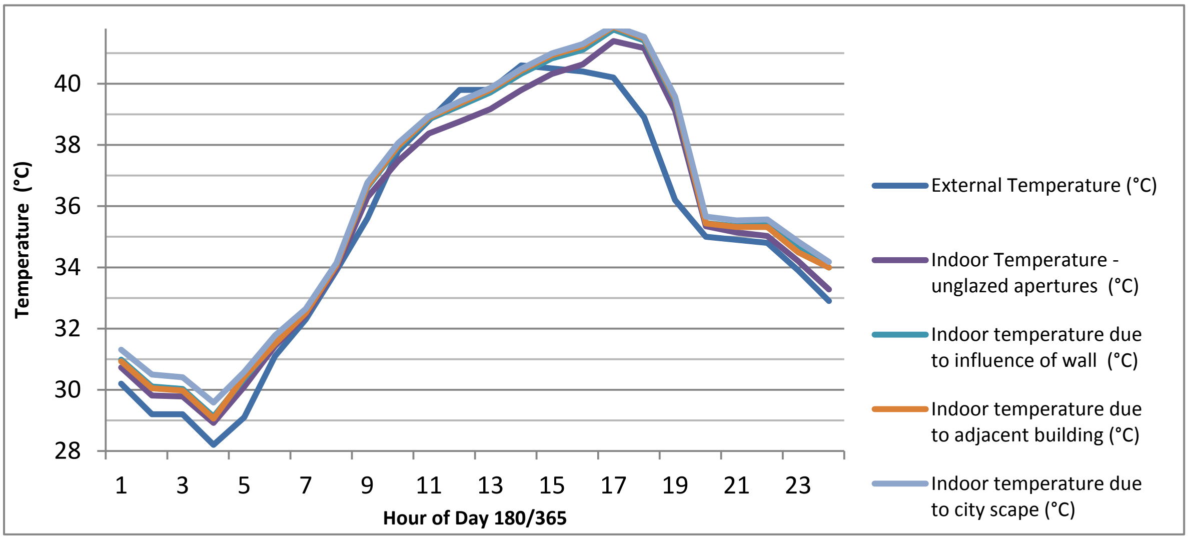

Figure 4 Simulated temperature for 24 hour period over day 180/365 (30th June). Unglazed apertures. Comparison of effect of urban-scape on the indoor temperature.

The environmental sensitivity of the building envelope:

Two preliminary simulations were undertaken for the purpose of developing a baseline for comparison. The first with all apertures opened for 24 hours, with the building unit as an unglazed shell, this simulation showed no significant difference between indoor and outdoor temperatures. The second with the glazed apertures closed for 24 hours where an increase in indoor temperatures by over 3°C signifies the negative effect of the glazed apertures within the building envelope.

In an attempt to mimic typical user behaviour of closing out the harsh intense heat of the day and opening up and airing the inside of the residence during the cooler night, a series of simulations were carried out where the apertures were opened for a few hours of the day. The simulations indicated opening the windows for a period of 12 hours, from 1900 Hrs to 0700 Hrs yields the most significant reduction in internal conditions with the highest indoor temperature (west facing areas) becoming 3.4°C lower than the outside There is however a time-lag between maximum indoor and outdoor temperature of 4 hours (see Figure 5).

The detrimental effect of glazed apertures on the indoor temperature (3°C) is significantly higher than the increase due to the effect of the urban micro-climate (0.6°C) hence further investigation is directed towards the building envelope. For the purpose of assessing the worst case scenario, all further simulations concentrated on the regions of the building most affected by solar gains: the west facing areas. The treatment of the apertures was scheduled as opened for 12 hours: 1900 to 0700.

Overcoming inappropriate glazing:

A simulation was conducted to compare the suitability of double glazed with single glazed apertures in a hot-dry climate. It was determined that double glazed apertures are climatically appropriate as they maintained an indoor temperature 0.5°C lower than single glazed apertures.

A series of simulations were carried out where the building was augmented with various shading devices. These included a 1m deep shade, 2.5m shade, and a 2.5m deep veranda (with walls enclosing the veranda space). A comparison of the effect of such shading devices led to the conclusion that while temporary respite may be achieved from direct sunlight and associated glare discomfort, the change to internal temperature within the building is negligible.

A comparison of the simulations undertaken indicate a reduction of the window area by 50% (to 15% glazing ratio) leads to an improvement of the indoor environment by over 2°C bringing the (maximum) indoor temperature down to 34.8°C –which is an acceptable indoor comfort temperature. The smaller window size results in a slower decrease in indoor temperature at night with the temperature remaining 2.5°C higher than outside temperatures (see Figure 5).

Augmenting passive control: Forced Ventilation

The passive control of the indoor environment is augmented with a degree of mechanical control through forced ventilation. The introduction of cool outside air into the indoor environment results in a reduction in temperature, however the intrusion of dust and insects necessitates control over the quality of air used for ventilation. A solution to this issue is in the form of forced ventilation whereby outside air may be filtered and forced into the indoor environment. This is a variation of the standard supply system of forced ventilation where outside air is brought in and creates a positive pressure (Szokolay, 2008).

The building is simulated to follow the schedule of apertures open during the evening hours from 1900Hrs to 0700Hrs and adjustments are made for an increased air change rate (as a means of controlling air velocity) during the same schedule to mimic the inclusion of forced outside air. Assuming the outside air speed to be 1m/s (the average air speed in Lahore is approximately 4.5m/s for July) (Weatherspark, 2013) the number of air changes through a $2m^2$ window (at 15% glazing ratio) and a room of $77m^3$, as simulated, is at 97. A conservatively applied air change per hour value of 50 results in a reduction to the internal temperature by 0.5°C.

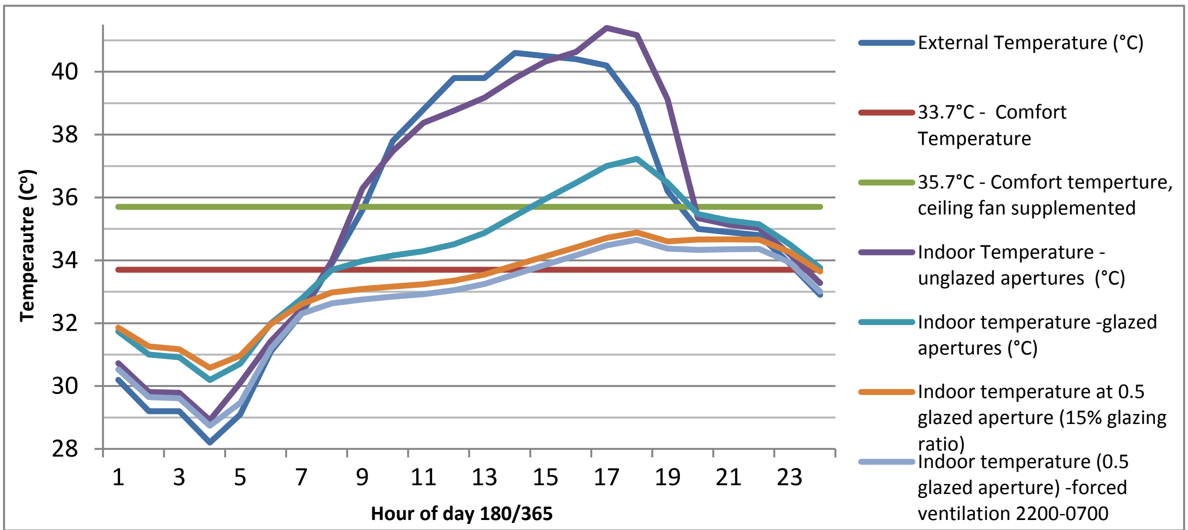

Figure 5 Simulated temperature for 24 hour period over day 180/365 (30th June). Comparison of change in temperature due to change in glazing ratio and with forced ventilation.

A slight modification to the schedule postpones the start of forced ventilation till 2200 Hrs when the outside air temperature has dropped to below 35^{o} with the result of the indoor temperature remaining between the comfortable values of 34.5^{o}C and 28.8^{o}C.

The 1st floor:

The difference between the indoor temperatures of ground floor and a similar space at the 1st floor region is an average of 1.1^{o}C which with the introduction of the passive and mechanical control measures listed above comes down to 0.5^{o}C. The result is a significant reduction in indoor temperatures for both floors and further reductions can be attempted by focusing on the insulating properties of the roof construction.

CONCLUSIONS

This paper has attempted to assess the role of building codes in establishing thermal comfort within the indoor environment. Focusing on hot-dry climates and taking Lahore Pakistan as a case study some shortcomings in the building code are identified, foremost of which is the absence of locally relevant thermal comfort parameters.

Taking the urban geometry and the building envelope as products of the building code, specific contributions of the indoor environment of a typical residential structure were studied through software simulations. The simulations indicated that the urban geometry has both a positive and negative effect on the indoor environment; the effect of the urban micro-climate being an increase in temperature while the close proximity of neighbouring buildings dampening this rise possibly due to their shading effect. The simulations further indicated that the building envelope is responsible for most of the heat gain to the interior of a building and that the primary contributor to uncomfortable indoor conditions are the glazed apertures within the building envelope. It was also determined that through a simple reduction to glazed surface area, augmented with low energy mechanical conditioning (such as ceiling fans and forced night-time ventilation) the indoor environment can be brought to within comfort levels.

The overall focus of the work has been upon the achievement of thermal comfort through the use of passive and low energy measures. The work indicates this is an achievable target for a sizeable section of the population, it thus contributes towards laying the ground work for modifications in building codes to achieve this objective.

ABSTRACT

Dhaka is a highly vibrant megacity with almost 15 million populations (World Bank, 2013). Due to high density in an undisciplined urban setup, the city is in real scarcity of open and green spaces for her large number of dwellers. The rapid growing population in conjunction with very immediate developing urbanization has led to unplanned and uncontrolled expansion of Dhaka which is resulted in the gradual loss of open and green spaces in the city. In the quest of meeting the great demand of urbanization, the city has hardly saved some of her natural spaces. Unfortunately these very few existing open spaces are not even well preserved with natural greeneries or vegetation; as a result this lack of green and plantation severely affects the microclimate of those spaces. Whereas the use of vegetation and plantation as an element of urban landscape, has always great environmental benefits and opportunities both in the scale of micro and global climate; like temperature control, solar radiation control, wind control, reduction of air pollution by absorption the pollutant and noise reduction etc. Urban vegetation minimizes direct solar radiation of the surface, optimizes wind velocity and its form and configuration influence temperature, air humidity and wind pattern of an urban setting. Vegetation create green barrier as visual boundary, natural screen and space buffer as a major element of landscape design.

The objective of this paper is to discuss the impact of vegetation in urban air temperature and explore the possibility of vegetation configuration to maximize the cooling effect in urban open space in Dhaka city. For researching these issues, a short field survey has done in two significant urban squares to find out the answer of the proposed research query. An evidence based microclimatic simulation software ENVI-met is also used to compare the outcome data of the field survey.

INTRODUCTION

Preface

The rapid growing population in conjunction with very immediate developing urbanization has led to unplanned and uncontrolled expansion of Dhaka which is resulted in the gradual loss of open and green spaces in the city. In the quest of meeting the great demand of urbanization, the city has been developing her infrastructure as well as built environment by continuous ignorance of nature which has hardly saved some of her natural spaces. Comparing with rural surroundings, this built environment of Dhaka city is mostly uncomfortable to her dwellers' experience. Expansion of unplanned urbanization and built structure results cutting a large number of trees and converts the green areas in concrete surfaces. A minimum 25% of forest cover is suggested for a healthy living (Mowla, 1984) where at present in old Dhaka (old part of the city) only 5% and new Dhaka (new part of the city) 12% of land is

Author A is a Lecturer in the Department of Architecture, Bangladesh University of Engineering and Technology, Dhaka, Bangladesh.
Author B is a M.Arch Student at McGill University, Montreal, Quebec, Canada.

green and open (Mowla, 2011). Green spaces with vegetation have great environmental benefits and opportunities. Vegetation has potential to reduce environmental temperature. Its form and configuration influence solar radiation, temperature, air humidity and wind flow of an urban setting. This paper states the impact of vegetation in urban air temperature and explores the possibility of vegetation configuration to maximize the cooling effect in urban open space in Dhaka city.

Statement of Problem

Use of excessive exposed hard surfaces like brick and concrete pavements and plaza, pitched road, buildings, air-conditioning system etc are responsible for raising urban air temperature. The urban spaces of a city are considered more vibrant when it can allow more people for outdoor activities. So it is important to create attractive and welcoming open spaces for the public, where outdoor comfort can be an important criterion. Again, air temperature is a vital aspect for this outdoor comfort. It is found that when meteorological data of average air temperature for Dhaka is 28 C (23 Feb, 2012) then the average air temperature of the paved area of Shahid Minar is 32 C (Field Study). Vegetation is an important element of nature. Being an organic element, vegetation has some impact on local microclimate as well as global climate. That is why this study is focused on the impact of vegetation in urban open spaces in Dhaka, in terms of air temperature.

Objective

The objective of this study is:

- To determine the impact of vegetation in open spaces in Dhaka city in terms of Air temperature.
- To find out the possibility of vegetation configuration to maximize the cooling effect in urban open space in Dhaka city.

Methodology

The methodology of this study can be described in three steps and these are:

Step 1: Literature Review and Theoretical Basis: Study the relationship between vegetation and basic four environmental components and the impact of vegetation on the open spaces from different paper, journal, books, articles etc.

Step 2: Field Study: A short field survey (in two urban open spaces) has been done in the current situation of Dhaka. This part is very important for this research because this research is based on field study and the output provides the current microclimatic data of the study area. Two urban spaces of similar context are taken for this study. The "Shahid Minar Chattar" (approximate area 120000 sft), located in the Dhaka University area and the "Pantha Kunja" square (approximate area 260000 sft), located beside the city commercial zone, Karwan Bazar node, Dhaka. Both spaces are laid in north-south direction and consist of both paved and green area. This step will find out the answer of the query, whether is there any variation of air temperature happened for presence of green vegetation and urban pave?

For data collection, 6 Points (spot) have been taken (in almost equal distance) on an imaginary line along the centre (north-south direction) for the both cases for measure the air Temperature, Humidity and Air Velocity. Here for Shahid Minar Chattar, lump sum 500 ft distance has being taken, where after every 100 ft one data point has located in the case study 1**(Figure 6 a)** and for Pantha Kunja, lump sum 1000 ft distance is being taken, where after every 200 ft in park area and every 100 ft in paved area, one data point has located in the case study 2 **(Figure 7 a)**. All data (18 set) have been taken on that imaginary line above 1m ground level with the Kestrel 3000 Pocket Weather Meter. The data was being taken on February, 2012 on morning 10.00 am, noon 1.00 pm and evening 4.00 pm.

Step 3: Simulation: Microclimatic simulation has been done by ENVI-met software to compare with the survey results. The full areas (draw in **Figure 6a & 7a**) of the two urban spaces are considered for ENVI-met modeling. Input data are found from field survey and weather data of Dhaka.

Limitations

A number of limitations have observed in this study, like time, resource and some practical problems. The survey for this study is held in the month of February where June to September are the hottest (considering highest temperature database) months for Bangladesh. During the survey it was very difficult to locate accurate point for measurement. Sometimes it was difficult for the users and different activities on the spots.

LITERATURE REVIEW

For this paper, urban space means that the space which is designed or created and used for deferent public activities in Dhaka and vegetation means the plants of an area or a region. Vegetations can be classified in different categories. In broader classification: Herb, Shrub and Tree. Herbs are seed-bearing plant whose aerial parts do not persist above ground at the end of the growing season where as Shrub is a woody perennial plant, smaller than a tree. Trees are any large woody perennial plant with a distinct trunk giving rise to branches or leaves at some distance from the ground. Again In terms of density, according to John P. Caouette and Eugene J. DeGayner, they are two types, Low (SDI < 280) and High (SDI > 280) (Caouette and DeGayner, 2008). Stand density index (also known as Reineke's Stand Density Index after its founder) is a measure of the stocking of a stand of trees based on the number of trees per unit area and diameter at breast height of the tree of average basal area.

Now the relationship of vegetation and four major components of the climatic features of environment, Solar Radiation, Air Temperature, Humidity and Air Flow discuses bellow.

There is close relationship between vegetation and solar radiation. According to Wardoyo (2011), individual leaves of the vegetation allow, some radiation to be transmitted through them (20%), absorb some radiation (55%), and reflect some radiation (25%). The leaf absorbed the solar radiation and re-transmitted it by evapotranspiration which increases relative humidity and reduces air temperature (Wardoyo, 2011). Large trees with spreading canopy can also provide shade and protect surface from direct radiation. Bueno-Bartholomei and Labaki found that, the structure of the crown, dimension, shape and colour of vegetation leaves influence reduction level of solar radiation (Bueno-Bartholomei and Labaki, 2005).

Vegetation in open space has low reflectance value that helps to reduce the air temperature in an urban surrounding. Vegetation does not radiate the long wave radiation which helps to maintain lower air temperature. Evapotranspiration reduces air temperature and increases relative humidity (Wardoyo, 2011). Tree shade also helps to reduce the air temperature. Zahoor (1997) in Pakistan found that vegetation has significant influenced to local temperature and effective in reducing air temperature about 6 –7 °F.

Again, according to Wardoyo (2011), vegetations also influenced the pattern of air movement through guidance, filtration, obstruction and deflection. Air movement sometimes depends on vegetation characteristic and configuration. Scudo (2002) establish that geometry, height, permeability and crown of the vegetation are the structural vegetal characteristic that influenced the controlling air movement.

Evapotranspiration reduces air temperature that increases relative humidity. It is found that relative humidity is always higher in the green areas.

Again the environmental criteria in Dhaka City are also important for this study. Bangladesh is in Warm Humid Tropics. Generally she has six seasons according to natural, cultural and social activities. But climatically, the climate of Bangladesh can be divided into four seasons. According to Hossain and Nooruddin meteorologically the climate of Bangladesh is categorized into four distinct seasons Winter (cool dry), Pre-Monsoon (hot dry), Monsoon (hot and wet), Post-Monsoon (hot and wet), where Winter months (December to February) temperature 21-26 C, Pre-Monsoon (March to May) temperature max 34 C, Monsoon (June to September) avg. 31 C, Post-Monsoon (October to November) temperature bellow 30 C (Ahmed, 1996). Average Relative Humidity is 60-80%. Radiation on a horizontal surface 5.00 kWh/ m2 and Air Flow 4.1 m/s (Ahmed, 1996).

The simulation tool, ENVI-met is a three dimensional microclimate model designed to simulate the surface, plant, air interactions in urban environment with a typical resolution of 0.5 to 10 m in space and 10 sec in time. Typical areas of application are Urban Climatology, Architecture, Building Design or Environmental Planning, just to name a few. ENVI-met is a prognostic model based on the fundamental laws of fluid dynamics and thermodynamics. (ENVI-met web)

FIELD STUDY

Case Study 1: Shahid Minar Chattar

"Shahid Minar Chattar" is a historically and culturally significant place for Dhaka city. This monument carries the memories of our language movements on 1952. This public space is a large hard paved area with small green and large trees. Green area is surrounded the main monument area. A number of paved stairs leading to the upper platform of the monument is an important public plaza for socio-cultural activities. There is no large structure along the monument. This area is completely exposed to the sun. 6 points are being taken for data collection, which are as follows. (**Figure 6**)

Point 01: Located in a Green space (soil) with tree shade behind the main monument.

Point 02: Located in Red Brick pave with no shade and no green. Higher than ground level.

Point 03: Located in Large Red Brick pave with no shade and no green.

Point 04: Located in a Green space (soil) with tree shade. There is pave around this area.

Point 05: Located in a Green space (soil) with tree shade. But beside the road pave.

Point 06: Located in the road pave.

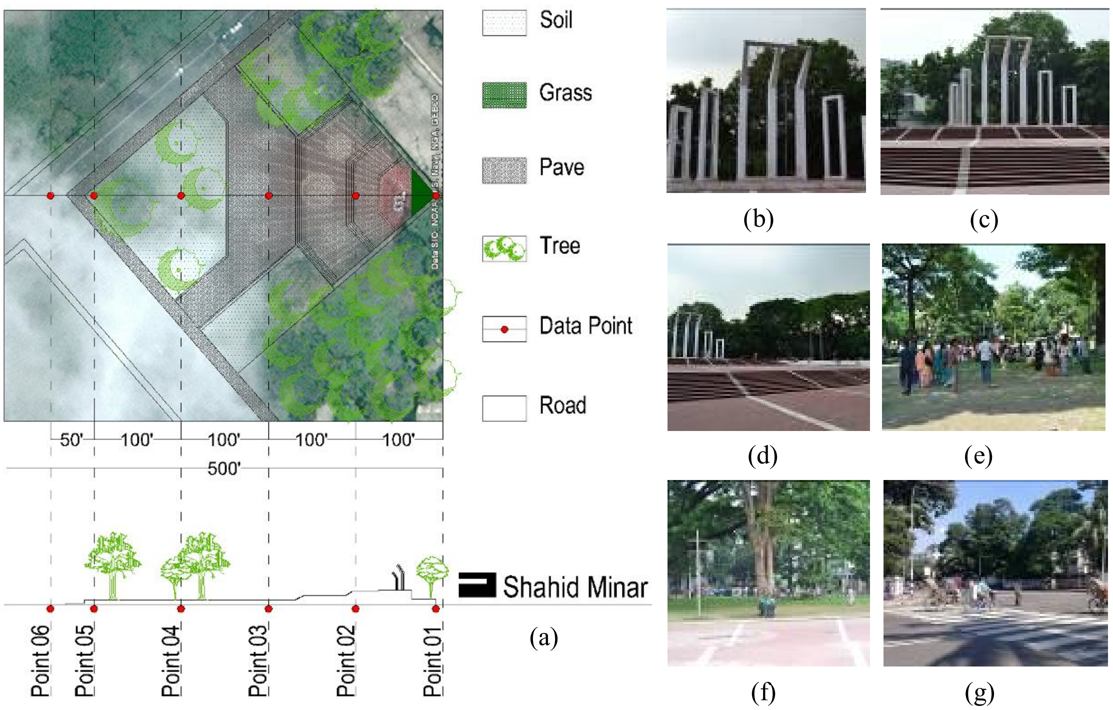

Figure 6 (a) Top view and section of Shahid Minar (b) Point 01 (c) Point 02 (d) Point 03 (e) Point 04 (f) Point 05 (g) Point 06

Case Study 2: Pantha Kunja Square

Pantha Kunja is the only open space cum green space in Karwan Bazar area, one of the important commercial hubs of Dhaka city. It has two parts: one is Green Park with large trees and limited pave area and another consists of large pave with small green area (herbs and shrubs). This area is also completely exposed to the sun. 6 points are being taken for data collection, which are as follows. (**Figure 7**)

Point 01: Located in a Green space (grass) with tree shade with little pave.

Point 02: Located in a Green space (grass).

Point 03: Located in a Green space (grass) with tree shade.

Point 04: Located in Large Yellow and Red Brick pave with no shade.

Point 05: Located in Large Yellow and Red Brick pave with no shade beside small green.

Point 06: Located in the footpath pave beside the road.

Results and Findings from Field Survey and Software Simulation

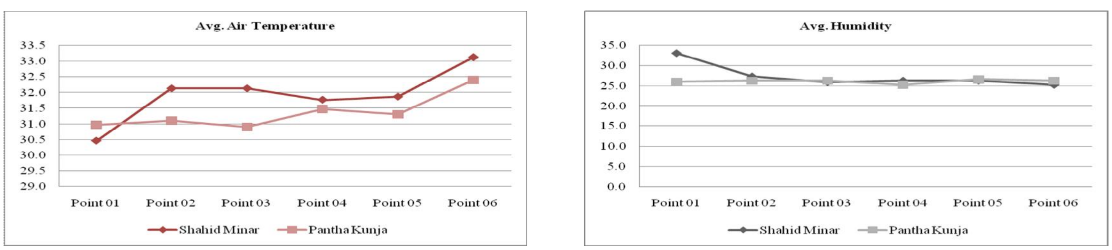

Figure 8 (a) Average Air Temperature Diagram (b) Average Relative Humidity Diagram

ENVI-met Simulation

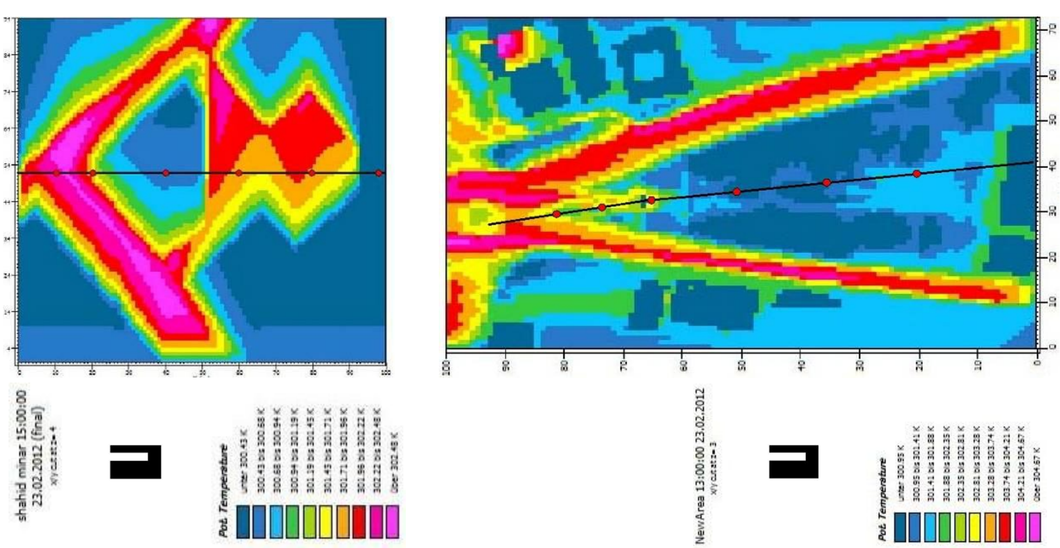

Figure 9 (a) Thermal Image of Shahid Minar Chattar (b) Thermal Image of Pantha Kunja Square

Here are the charts of average value of Air Temperature and Relative Humidity which are being found from field data **(Figure 8)**. For ensuring human comfort in any urban context, relative humidity is equivalently relevant and important with temperature. That is why, in field survey, Relative humidity has always taken in consideration for analytical observation.

VEGETATION AND OPEN SPACE CONFIGURATION

It is found from Case study 01 and Case study 02 that air temperature in a green space is remarkably less than a paved or built space in Dhaka city. In Case Study 01, Average Air Temperature in green area varies from 30.5 C to 31.8 C where in paved area varies from 32.1 C to 33.1 C. In Case Study 02, Average Air Temperature in green area varies from 30.9 C to 31.3 C where in paved area varies from 31.5 C to 32.4 C. Here some other issues can be considered as follows.

Orientation: An imaginary line is taken through Case Study 01 considering north south direction. In our country the wind flows from south east direction in summer. So point 01 is 30.1 C which is less than point 04 and point 05 (31.8 C and 31.9 C) for the wind flow through the plaza area from south. Again an imaginary line is taken through Case Study 02 in same north south direction. In this case the large green is in the south part of the square which create cool environment in pave area on north.

Shade: The shaded area of green space is much cooler than the exposed area. Shade can provide by large trees or other minimal built objects. In Shahid Minar point 01 is always shaded by large dense trees. So the air temperature in point 01 is always cooler than other green spaces. In Pantha Kunja point 02 is exposed to the sun. As a result air temperature in point 02 is higher than point 01 and 03.

Types of vegetation: It is also an important issue. In Shahid Minar, there are small numbers of trees founded in selected green area. There are a few grasses found during this survey. There is no herb, shrubs and trees in the paved area. In Pantha Kunja, there are herbs, shrubs and trees founded in the park area with grasses on ground which helps to reduce the air temperature as per survey data. In the pave area there is also small green area founded with herbs which might helps to reduce the air temperature.

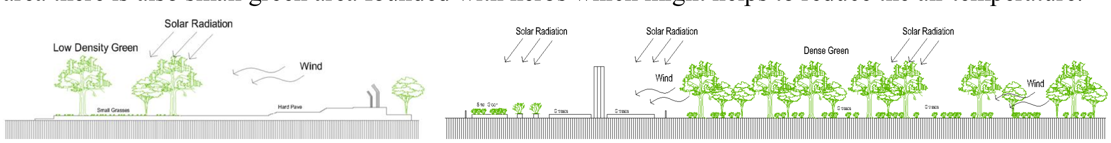

Figure 10 (a) Section of Case Study 1, Shahid Minar; (b) Section of Case Study 2, Pantha Kunja Square

Vegetation Density: Vegetation density also effects the cooling. More dense vegetations increase Evapotranspiration, which reduces the air temperature. Pantha Kunja green area is denser than the Shahid Minar green area and it is also a cause of less average temperature in Pantha Kunja.

Area of the Vegetation: In Shahid Minar almost 80,000 sq ft green area and 40,000 sq ft in pave area where as in Pantha Kunja 240,000 sq ft green area and 20,000 sq ft pave area. Average temperature in Pantha Kunja is less than the Shahid Minar area (survey). Larger area of vegetation contributes in better cooling effect.

Surrounding Vegetation and Presence of Built Objects: Surrounding area has also an impact in the air temperature. Here surrounding area is not considered enough. For Shahid Minar, if a 500 ft diameter circle is considered, more green area with few built area are found which has a cooling impact on local air temperature. In Pantha Kunja if a 1000 ft Diameter circle is considered, more exposed pave and glaze area with more built structure are found.

Vegetation and Relative Humidity: Relative Humidity is much related component to air temperature. As per graph **(Figure 8(a) & 8(b))** air temperature and humidity varies in vice versa. Temperature rise is responsible for reducing the relative humidity. In this study the relative humidity data has also taken for observation.

OBSERVATION

Vegetation has tremendous impact on local microclimate. From the observation of this study some points can be illustrated as follows:

- Presence of vegetation minimizes direct solar radiation and reduces microclimatic air temperature (3C - 4C) in an urban space.
- As wind flows from south east in Bangladesh (generally), vegetation locating in south can help to reduce the air temperature on the pave locating in the north.
- Large and dense trees create shade. Air temperature is less in the shaded space than an exposed area (1C – 2C). Even air temperature in the shaded pave is less than the pave exposed to the sun.
- Air temperature also depends on types of vegetation used in a space. Types and configuration of herbs, shrubs and trees are important for local air temperature.
- Density (trees) is also an important component for reducing air temperature. Dense vegetation helps to reduce air temperature by screening solar radiation.
- Area of vegetation affects the local air temperature. Large area of vegetation can keep lower the air temperature where as presence of hard exposed material or structure in the green area is responsible for increasing the air temperature.

CONCLUSION

The urban open spaces are very vital part of a city and considered more successful when these spaces can allow more people for different outdoor activities. So it is always very essential to design comfortable urban spaces for city dwellers. Dhaka is a city of hot and humid climate with high average temperature. Direct solar radiation and scorching heat of sun not allow city people to have maximum use of city open spaces specially in day time. Vegetation has great potential to reduce this air temperature (3C - 4C) of urban microclimate and ensure sustainable breathing space. Again vegetation creates shaded cool area with lower air temperature for the users. Designing an urban space with large area of vegetations on south side may create comfortable environment. Vegetation configuration can be one of major determining factors to get benefit of urban open spaces in Dhaka city with the best utilization of it, in her every aspect of urban landscape design.

ACKNOWLEDFEMENT

The research was started for a term paper of a M. Arch course, Arch 6106: Eco System and Built Environment. We want to thank the course teacher Prof. Dr. Qazi Azizul Mowla. The further research simulation was inspired by another M.Arch course Arch 6105: Design in the Tropics by Prof. Dr. Khandaker Shabbir Ahmed.

Exploring the Current Practices of Post Consumer PET Bottles and the Innovative Applications as a Sustainable Building Material – A Way Ahead

Arulmalar Ramaraj, B.Arch, M.T.P. *[Sathyabama University]*

Jothilakshmy Nagammal, B. Arch, M. T.P, PhD *[Sathyabama University]*

ABSTR ACT

PET stands for polyethylene terephthalate and PET bottles are occupying an indispensable position in common man's life. Food processing industries across the world are using PET bottles as effective containers for storing juice, beer, carbonated and non carbonated drinks. The different parameters which determine the form of PET bottles during designing, manufacturing and production phases are cost per unit, need, volume, color, intrinsic velocity, size, shape etc. Irrespective of a wide range of applications, initiatives in recycling post consumer PET is sporadic. The disposal of PET bottles in the environment, significantly contributes to ecological imbalance. Interpreting the negative impacts and adopting the principles of Reuse B and C by Romans, pioneers are searching for rational and technical solutions to check this issue. In construction industry, hybrid actors are using PET bottles as moulds for developing alternative blocks. Technocrats are recycling PET products physically in to fibers, pellets and flakes for partial replacement of fine and coarse aggregates in conventional building materials. This paper intends to consolidate such initiatives addressing building systems, materials and artifacts. It discusses an overview of such applications and other intuitive trends which are emerging in Indian context.

INTRODUCTION

The technology of storing liquid products for transportation, distribution and use is defined as packaging. Our ancestors used baskets and storage units made of natural fibers and indigenous materials like stone, earth etc. Use of paper and metal plated containers for such applications dates back to the 10th century (Packing, 2012). Glass bottles, plastic containers and polyethylene are used predominantly in today's context. Polyethylene terephthalate, a versatile material is playing a primary role in packaging industry in today's context, simultaneously increasing the production process. The drawbacks during the disposal phase is raising a question, whether the invention is a boon or a bane, revolving around the societal benefits (Andrady & Neal, 2009) and the negative impacts in the environment (Webb, Arnott, Crawford, and Ivanova, 2012).

HISTORY

According to the archaeologists, a novel concept, "Post consumer packing material as a resource, specifically in construction", is traced from the Hellenistic age. Interpreting the problems posed by disposal of 'amphorae', Romans came up with an innovative idea to reuse them in architecture (Will,

Arulmalar Ramaraj is a Research Scholar in the Department of Architecture, Sathyabama University, Chennai, Tamilnadu. Jothilakshmy Nagammal is a Professor and Head, Department of Architecture, Sathyabama University, Chennai, Tamilnadu.

1977). While doing so, the pointed base pots were either modified or unmodified. Romans classified reuse as A, B and C (Pena, 2007). When the amphorae were used as a storing unit, it was reuse A. Reuse B and C, denoting the applications in other fields without modification and with modification respectively. The beginning of 19th century witnessed similar application of glass and PET bottles in construction.

AN INSIGHT TO PET

Plastic is a commonly preferred packing material for various goods in today's fast moving contemporary world. They are classified in to seven categories based on recyclability (Society of plastics, 2013) and polyethylene terephthalate denoted as PET, PETE or PETP ranking number one. The credit of inventing PET goes to chemists Whitefield and Dickson, the employees of Calico Printer's Association in 1941 and was patented only in 1973 by Wyeth. Semi crystalline thermoplastic polyester, durable, low gas permeability, chemically and thermally stable, easily processed and handled, transparent, wear and tear resistant and non biodegradable are the general characteristics of PET. Based on its versatility, it is primarily used in textiles, films, utility ware, sportswear etc. Food processing industries prefer PET as it is hygienic, strong, lightweight (Petresin, 2013) and devoid of phthalates, dioxins, bisphenol A, cadmium, lead and other endocrine disruptors (NAPCOR, 2013). As PET is used predominantly in the form of bottles for storing carbonated and non carbonated drinks, this paper addresses to reuse the PET bottles in construction industry.

PET BOTTLE

Cap, neck, shoulder, body, hip and feet are the basic parts of a PET bottle (bottle biology, 2013). Containers for storing carbonated and non carbonated drinks have different intrinsic velocity, wall thickness, color and level of copolymer. With respect to the physical form, PET bottles used for storing carbonated drinks are designed with an additional twist in the neck, thicker wall, higher intrinsic value, lower copolymer level and a petaloid base (Bristogianni, 2012).

POST CONSUMER PET – REUSING VS RECYCLING

According to the Environmental Protection Agency, recycling, incineration and landfill are the general ways of disposing plastics are disposed in today's context. Each method has its own disadvantages and drawbacks (Webb et.al, 2013). Its disposal is disturbing the ecological balance, directly or indirectly affecting the health of all living creatures (Rustagi, Pradhan & Singh, 2011).

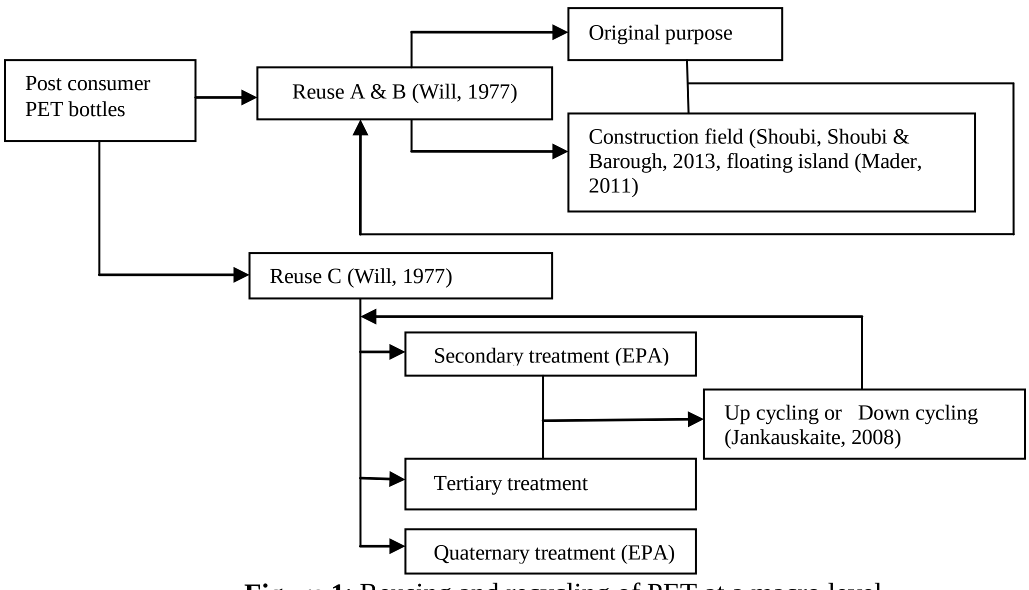

Figure 1: Reusing and recycling of PET at a macro level

Recycling is classified as primary – re extrusion of pre consumer scrap; secondary or physical or mechanical treatment; tertiary or chemical treatment where the chemical structure is altered and quaternary treatment, focusing on energy recovery. Reusing is the most preferred option as the consumption of energy and resources are always less (Al-Salem & Baeyens, 2009) as in Figure 1.

Reusing PET bottles for packing continuously is not preferable; however the idea of reusing them in a different field requires innovation. PET bottle bricks as an alternative building material, a less energy intensified process, is successful in construction process. A rational and a pragmatic perception is the requirement in today's context to address multifaceted issues simultaneously.

POST CONSUMER PET AND THE AVANT-GARDE PERCEPTIONS

Innovators and researchers are adopting different strategies to reuse and recycle PET bottles. Up cycling and down cycling are the processes involved in the manufacturing of new products with the treated PET bottles. While applying such concepts, the consumption of energy and the negative impacts generated during the production phase need to be kept to the minimum. Investigations on effective reusing or recycling of such used bottles in the construction sector, marks the beginning of the next industrial revolution. A holistic, pragmatic approach rich in aesthetic values (Pramar, 1973), as the focal point, the vision of the architects and environmentalists, technocrats, product designers and artists are interpreted in Table 1.

Table 1: Unique perceptions

Post consumer PET bottles	Hybrid actors - Holistic	Technocrats- Rational approach	Product designers- Innovations	Artists-Aesthetic expressions
Unmodified / Reuse B Modified / Reuse C (secondary and tertiary)	Partly objective and subjective, Aesthetic values	Objective, Economical, Utilitarian	Subjective, Partly functional and Emotional	Subjective, Aesthetic, Emotional
Approach	Ecocentric	Problem solving	Transforming the overlooked	Promoting Awareness
Examples	Bottle bricks with different fillers, PET bottle as a filler	Partial replacement in building materials	Screens, lamp shades, planter boxes, chandeliers, furniture etc	Murals, sculpture

EXPLORING THE 'ECOCENTRIC' APPROACH

'Ecocentric' approach is one among the six competing logics of sustainable architectural practices - built forms are parasitic in nature and revolve around the post consumer waste (Guy &Farmer, 2001). With self sufficiency and incorporating the principles of a living organism, Reynolds designed 'earthships' in 1970s. With his attitude towards post consumer waste as a resource, he developed building systems by using tires, glass bottles and aluminium cans. Creating the base for a man made floating island (Mader, 2011) with PET bottles is an exceptional eco centric idea.

Interpreting the role of PET bottles and 'Reuse B'

Following Reynolds' strategies, Froese initiated to construct small structures with PET bottles firmly held in position with nylon ropes in 2001 (Pachecho, 2013). PET bottle buildings are bio climatic, cost effective, non brittle, easy maintenance, resistant to abrupt shock loads; strong, durable, versatile, easy handling and reusable are the characteristics of such built structures (eco tec, 2002). Habitable spaces, activity centers, learning centers and latrines are constructed using PET bottle bricks at Honduras, Nigeria, Central America, Philippines and India. Architects and technocrats are searching for a variety of solutions to reuse post consumer PET bottles in building envelopes for permanently built forms, temporary structures and interiors as in Figure 2.

With a holistic approach, PET bottle bricks are being made with a variety of filling materials such as adobe or sand (eco tec, 2002, May 4), liquefied adobe, inorganic waste (Saraswat, 2013), sand and cork (Shoubi et al, 2013). PET bottles are stacked one on top of the other to build green houses (Alvarado, 2010). When adobe is used as a filling material in PET bottles, it should be tightly compacted with a stick as well as a compressor and then tightly closed (Can steel, 2014).

A unique brick with PET bottle itself as filler (Mehta and Ellis, 2007) is developed by Lima. Bottles are effectively used to replace the concrete in roofs and investigations on the monolithic casting of such discarded transparent containers is in the progress (Radu & Christiana, 2011) and as fillers in slabs (Pandya, 2012) as shown in Figure 2.

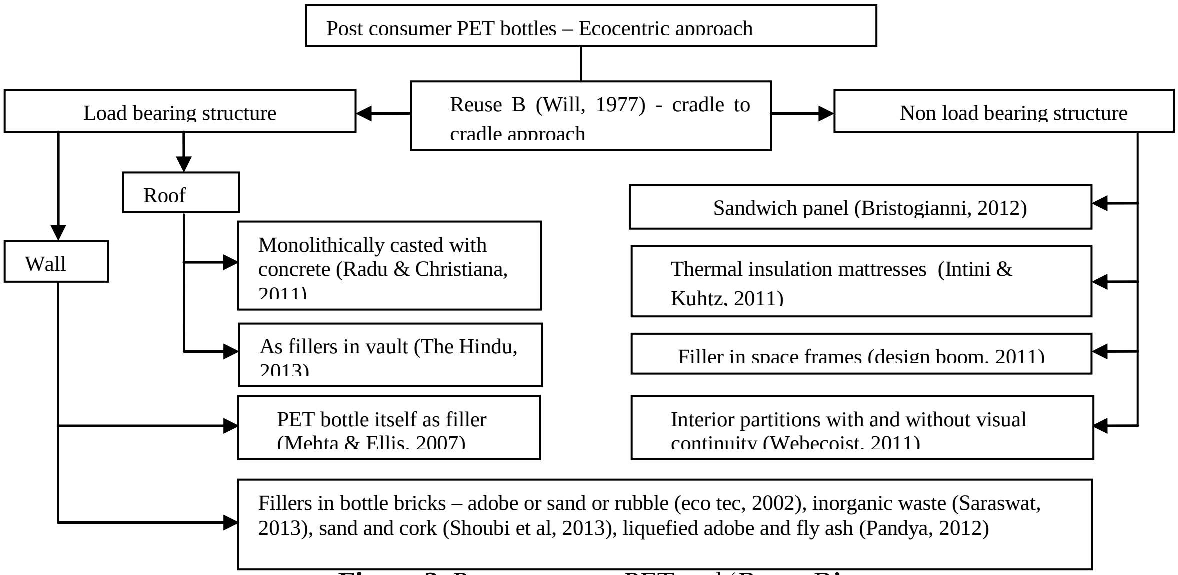

Figure 2: Post consumer PET and 'Reuse B'

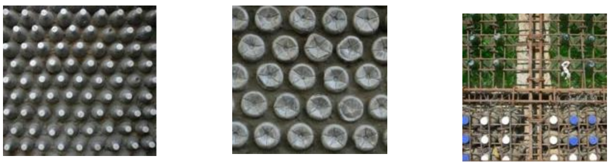
They are used as sandwich panels in the constructing emergency shelters (Bristogianni, 2012), as partitions with and without visual continuity and also as fillers in concrete roofs and space frames changing the perception of 'post consumer packaging waste. PET bottle partitions, designed in Danone office and in Morimoto restaurant, is a value addition initiative. In Morimoto restaurant, experiencing the two storied partition integrated with LED lights is a unique idea, bewildering the visitors to think about the workmanship and material (webecoist, 2011).

PET bottles and 'Reuse B' in Indian context

In a country like India the development is uncontrolled, unorganized, use of virgin construction materials increasing day by day increasing the proportion of the shelterless. Architects and others are adopting the ideals of ecocentric practices, zoning on the experimentation (Chan,2007) with post consumer waste. According to Antonoides (1992), materials are the flesh, bones and skin of the built forms and are categorized based on their influence on the structure and function. Initiators like Yatin Pandya, Prashant Lingam and Patrick San Francesco are the eye openers to experiment with post consumer PET bottles in constructing small scale buildings like activity centers, learning and habitable spaces for social causes in different Indian contexts.



(a) (b) (c)

Figure 3: (a) Front elevation (b) Rear elevation (c) PET bottles as fillers in roofs

A multi activity center at Ahmedabad by Yatin Pandya, Principal architect, Footprints EARTH, firmly believing in recycling waste as environmental, economic and architectural imperative as one of the sustainable principles, is playing a vital role in building the centre with waste materials. PET bottle bricks filled with fly ash are one of the materials for the envelope. A technique of using PET bottles as fillers in flat roofs and as bricks in walls integrated with aesthetic values as in Figure 3.

Hyderabad based entrepreneurs Prashant Lingam and Aruna, designed a prototype shelter using bamboo and PET bottle bricks covering an area 225 square feet. Bamboo is used as structural members and nearly four thousand PET bottles with earth is used in the construction. A typical bonding with bottle bricks is shown in Figure 4. They are aspiring to promote this as a model house under Indira Awas Yojana, a scheme initiated by the Government of India for housing.

(a) (b)

Figure 4: (a) A model house (b) a typical course of PET bottles

In Delhi, a learning centre as shown in Figure 5 was constructed by a non government organization, 'Samarpan Foundation' founded by Mr. Partick San Francesco using six thousand PET bottles with a prefabricated roof. A typical bonding is developed using one liter bottles for walls as well as flooring. The designed space roofed with simplified steel trusses and prefabricated sheets.

(a) (b) (c)

Figure 5: (a) Alternative courses with PET bottles (b) PET bottles and flooring (c) School

A model house of area 250 square feet is constructed using PET bottle bricks in Chennai. Figure 6 shows the unique bond developed by the Foundation, replacing steel reinforcement with 3cm X 3 cm Nylon 6, to improve the tensile strength. Techniques for constructing a vault and flat slab using PET bottles are developed. For the construction of one cubic feet volume of load bearing wall we require sixteen half liter bottles and nine one liter bottles.

Figure 6: (a) Typical course (b) Typical section (c) L Junction (d) 3cm X 3cm nylon 6 for additional tensile strength (e) Vault construction (f) Flat slab (g) A housing prototype

In our University Campus, we in collaboration with Samarpan developed a typical bond for the construction of a compound wall as shown in Figure 7. Further, PET bottle columns, where three half liter bottles and one liter bottles are stacked vertically in a typical course with nylon 6 as the reinforcement, runs around the column in clockwise and anticlockwise direction as shown is casted at the Council of Scientific and Industrial Research, Chennai for structural and seismic investigation.

ROLE OF PET IN 'REUSE C' FOR DEVELOPING ALTERNATIVE BUILDING MATERIALS

Innovative applications of physically recycled post consumer PET

The secondary recycling is classified as physical reprocessing, melting and reforming. Investigations on mechanical, thermal, electrical, light weight properties of such materials with physically modified PET granules, pellets, fibers as partial replacement for fine or coarse aggregates are progressing. Such developed materials and composites are effectively used in pavement and roads.With respect to melting and reforming or re engineering, PET bottles with inherent interlocking property are designed and developed by Miniwiz with properties like translucent, insulating, light, strong and mechanically recyclable material. It is created in order to tackle three environmental problems – waste accumulation, resource scarcity, greenhouse gas emissions simultaneously (Hegenwald, Ackermann, Neugebaue, Finkbeiner, 2013). Reusability, recyclability, non toxicity, low volatile compounds, on site production, scratch resistant, easy maintenance, simple installation and affordability are the distinctive features of this building material (Miniwiz, 2011).

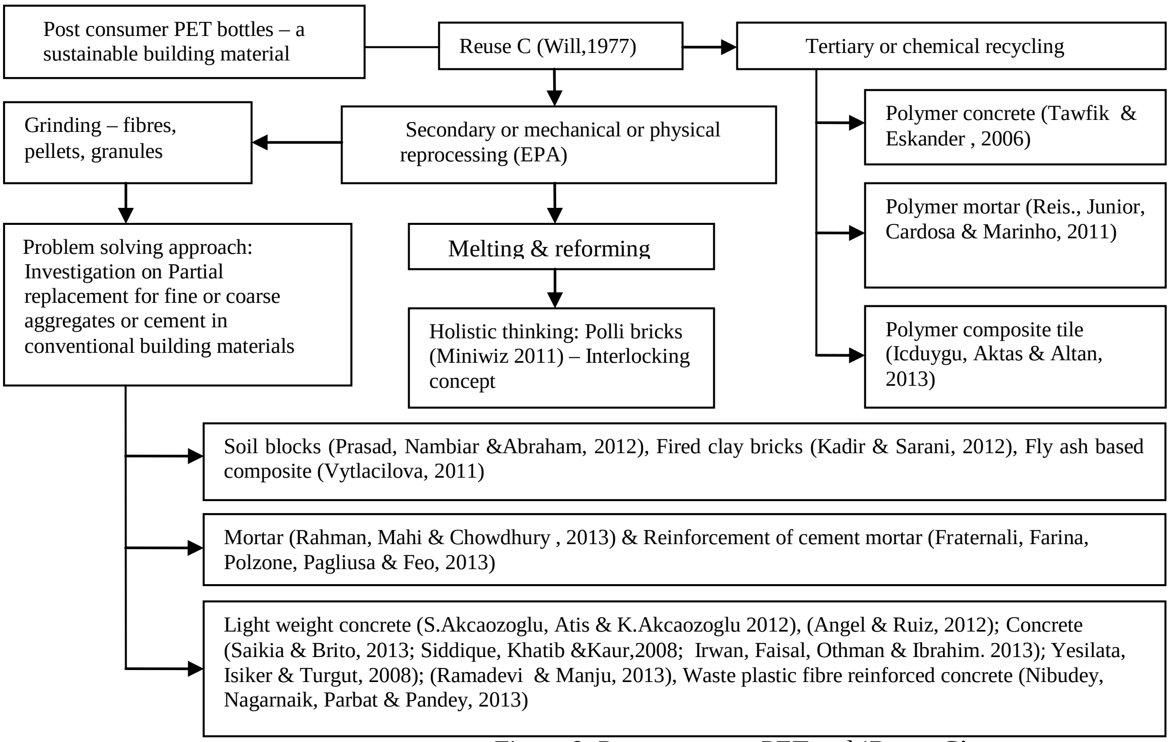

Figure 8: Post consumer PET and ‘Reuse C’

Innovative applications of chemically recycled PET

Investigations on polymer concrete (Tawfik & Eskander, 2006), polymer mortar (Reis et al, 2011) or polyester composite tiles (Icduygu et al, 2013) are emerging, where the chemical composition of the PET is modified through chemical treatment as in figure 8. Applications in the construction of habitable spaces need to be addressed and impacts created during the treatment and production phase is to be investigated.

CONCLUSION

The initial perception on the use of PET bottles in construction is changing day by day. A paradigm which emerged as PET bottle bricks in the construction of load bearing walls with steel trusses and prefabricated metal sheet is at present witnessing flat roofs with nylon 6 replacing steel reinforcement and intuitive vault construction. Apart from this ingenious bonds and columns using PET bottles gives a new direction to think about beams, foundation and simple trusses. With a holistic approach, designing phase of PET bottles with interlocking property is innovative. Even though research on the effective use PET in developing new material as an option, solutions exploring the application of PET bottles as structural members, foundation, retaining walls and secondary elements like street furniture, kerbs, road dividers, pavements and other landscape elements is to be looked in to. Strategies, approaches and practices integrating the relationship incorporating a total rethinking on junk as a resourceful building material integrating waste need to be nurtured and shall be enhanced. The Governing bodies shall formulate policies to propagate this eco centric approach via appropriate practices, research investigations on the properties of the materials and construction techniques.

ABSTRACT

The paper describes the climate, the thermal comfort and the key points to strengthen the buildings' climatic adaptability in Lingnan area of China, which is a part of the geographical distribution of the world's hot and humid area. Based on this, it makes a summery and extension of some general possibilities for passive energy efficient retrofit of existing buildings in humid tropical area.

At present there are around 50 billion Sqm existing buildings in China. Most of these have some problems such as high energy consumption, conflict between function and space, and improvement demands for environmental condition. It is practically significant to discuss the energy efficient retrofit under reasonable cost control.

There are passive technology and active technology in energy efficient retrofit. Passive technology means certain architectural methods that make the buildings stronger in regulation and adaptation to the climate. It is low-skilled, less in investment, easy to manage, as well as universal and durable, therefore suitable for low-cost promotion in large number.

The Lingnan Humid Tropical Area has similar climatic characteristics, such as hot summer and warm winter, humid climate and abundant rainfall. One significant is that the high temperature and the humid weather come up almost over the same period. The buildings have similar features in passive design for climatization, therefore there are certain rules to follow.

The paper introduces a case of energy efficient retrofit in this area, and sum up several passive technologies used in the case, and evaluates how it affects on economic and environmental benefits.

Finally, based on this, the paper makes a summery and extension by listing several strategies for existing buildings passive energy efficient retrofit in humid tropical area, and generalizing several passive energy saving possibilities on four different level: environment, space organization, material and structure, use and management of the buildings.

Humid Tropical Area, Existing Buildings, Passive Technology, Energy Efficient Retrofit, Lingnan

PRESENT SITUATION OF EXISTING BUILDINGS AND THE NECESSITY TO RETROFIT

According to a statistical data from the “Existing Buildings Retrofit Evaluation Criteria” preparation group of China Academy of Building Research in June 2013, there are around 50 billions square meters of existing buildings in China. Most of these have some problems such as high energy consumption, conflict between function and space, and improvement demands for environmental condition. Strategies need to be taken to ameliorate the situation immediately.

Buildings in developed countries have got long service life and always been reused well. In America, buildings have an average service life of about 80 years. Over 70% of the construction works are related to old buildings reuse. However, the number in China is shorter than 30 years. Annually, demolition of old buildings equal to almost 40% of the new construction area. There is 0.8t carbon being released when 1 ㎡ new area is constructed. As a result of the rapid urban development and updates, recurrent demolish and construction of building industry, It has been a vicious cycle of resources waste and environmental pollution. Appropriate retrofit of existing buildings can bring lots of positive results, such as less investment, shorter construction period, cost saving, environmental improvement, construction waste reducing and the low-carbon business.

BRIEF INTRODUCTION FOR PASSIVE TECHNOLOGY

Generally, there are passive and active technologies in energy efficient retrofit. Passive technology means architectural methods that make buildings stronger in adaptation to climate. It relays on natural energy such as sun radiation, to satisfy normal operation and improve the indoor comfort. It requires organize the building elements such as function and form synthetically. These measures are closely related to the site environmental and climatic conditions, so manifest in various forms in different area.

It is low-skilled, less in investment, and easy to manage, as well as universal and durable, therefore suitable for low-cost promotion in large number. However sometimes we need additional active technology to make up for its deficiency to regulate. Energy efficient retrofit of existing buildings should mainly relay on passive technology and supplementary on active technology. In long-term practice, Lingnan traditional villages have accumulated lots of experience, which inspire us today, “cold lane” e.g. It is a narrow alley between two rows of folk houses in Lingnan traditional villages. Together with those patios and courtyards system in the houses, it plays an important role for sunshading and ventilation.

CLIMATIC CHARACTERISTICS IN LINGNAN HUMID TROPICAL AREA

Lingnan Area is a place in South China which is next to the equatorial. It contains Guangdong and Hainan Province, southern Fujian and eastern Guangxi Province, which is across the mid subtropical, south subtropical and tropical areas. (Figure 1)

This area has a long and hot summer but short and warm winter. The annual sunshine hour is around 1800h to 2100h, which ranges from 40% to 50% in full year. The sunshine period is not long but both direct radiant and scattering are intense. The annual noon minimum incidence angle is about 41° . The average air temperature is 21℃ to 24℃ in full year, 28℃ to 29℃ in the hottest month, and 14℃ to 17℃ in coldest month. Extreme maximum temperature can reach 38~42℃. There is abundant rainfall, around 1700mm annually. The monthly air relative humidity is 65% to 85%. The hot and humid weather come up almost over the same period, from April to October.

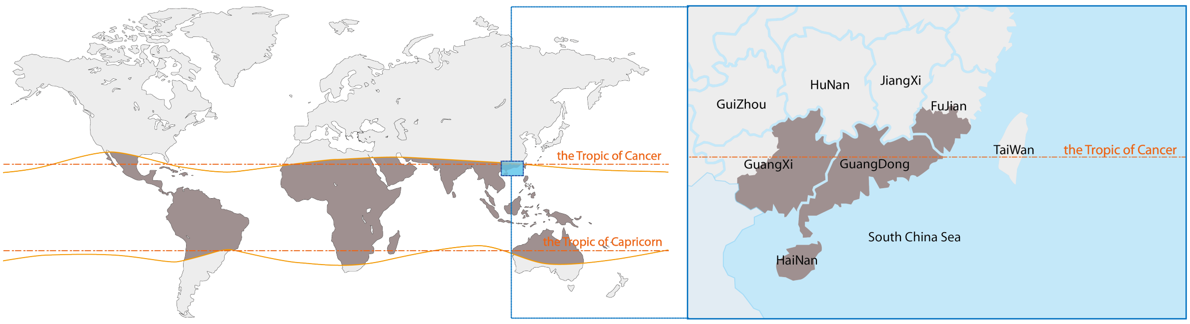

Figure 1 Location of Lingnan area in geographical distribution of the world's hot and humid area.

KEY POINTS FOR BUILDING ENERGY SAVING IN LINGNAN HUMID TROPICAL AREA

Lingnan area is close to the equatorial, so the solar radiation is intense. Therefore sunshading is needed to prevent the buildings from being heated directly. The summer is humid as well as hot, so that all outward interfaces are heated strongly by scattering. Therefore it is necessary to improve the thermal performance of the building envelope. Ventilation can help to bring away the heat as well as prevent moisture indoor. Furthermore, cooling down the building and its circumstance is good for improving the thermal environment of activities space. Sunshading, insulation, ventilation, cooling are the key points to improve the thermal environment. Other measures such as daylighting also help to save energy.

CASE STUDY: ENERGY EFFICIENT RETROFIT OF THE HEADQUARTERS OF CHINA MERCHANTS PROPERTY DEVELOPMENT CO.LTD

Case Overview

The project is located in Shenzhen. Originally it is a factory of RC frame structures, built in 1980, with 4 floors and a total construction area of 16200 Sqm. It used to be a factory of SANYO for producing electronic products, until the company moved out in early 21th century. Later the empty building was acquired by the China Merchants Property Development co.ltd and transformed into an office building for 500 employees. The retrofit design carried out from 2006 to 2007 before the project was completed in June, 2008. After the project, the building has 5 floors and a total construction area of 24260 Sqm, including 4600 Sqm area of parking garage. (Figure 2)

Figure 2 Location of the Headquarters of China Merchants Property Development co.ltd.

Design Strategy

The design strategies used in this project include both passive and active technologies. The former can be summed up on four levels. (Figure 3, 4)

1. Environmental level. Strategies include: increase the green, set up artificial wetlands and a landscape pool, use water-seepage ground material, create a three-dimensional green area on the retracted roofs in north side. These methods bring about a cool protective layer that can reduce thermal radiation to indoor.
2. Space organization level. By removing part of the original floor, the building obtains high space on outer layer, which will not affect the indirect lighting for inner rooms. The atrium in the middle helps to improve ventilation and lighting.
3. Material and structure level. The building uses fixed level sunshading panels made of silver-white metal in south facade, inner roller shutter windows in east facade, boston ivy with steel mesh as eco-shading in west facade. Hollow Low-e glass is used for the glass curtain wall. Those reserved original 240mm clay walls are added with aerated concrete block inside and coated with light-colored exterior paint. Solar panels are arranged on roof, which make use of solar and act as roof-sunshading simultaneously.
4. Use and management level. Those rooms that are less frequently used, such as multifunctional hall, are arranged on the upper layer, as a thermal insulation layer. The same principle is used in the meeting and reading rooms in south side. A high exhibition hall is added to the north, which contributes to promoting ventilation. The parking garage in basement makes good use of the spaces of poor lighting and ventilation. The office is disposed inner, surrounding the atrium.

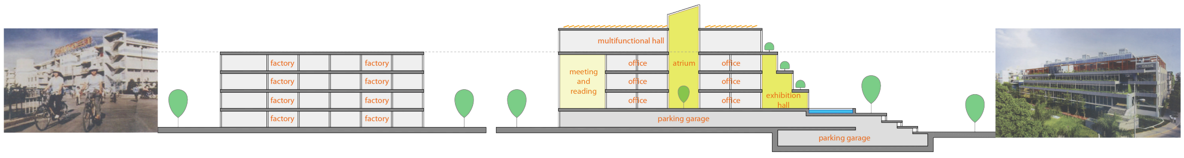

Figure 3 Photos and Sections before and after the Retrofit

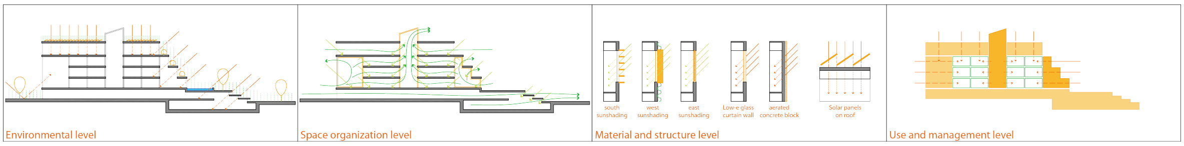

Figure 4 Design Strategies on Four Levels

The retrofit also uses several active technologies, such as air-conditioning fresh air system, high-efficient lighting, energy-saving elevator, etc. These methods also make great effects.

Energy Saving Effect

Considering the building energy consumption characteristics of this region, the air conditioning energy consumption is selected as building energy evaluation index. This building contains 16259 Sqm air-conditioning area. It's equipped with 1 High temperature chillers, 9 liquid desiccant dehumidification new air units, 350 dry fan coils, 1000 Sqm cold radiation capillary, and 2800 Sqm VRV multi-unit air conditioner. According to the building energy consumption monitoring data provided by the China Merchants Property in 2011, the Total annual energy consumption of unit construction area is 66.7 kwh/ Sqm•y, while the number of the other Grade A office buildings in Shenzhen is around 140-200kwh/㎡•y. It means that the total building energy-saving rate has reached 52.4%-66.7%. According to an energy simulation calculation by DEST and DOE2, about 27.3% of the energy-saving rate is obtained through passive methods. Using passive way in this retrofit project contributes to saving around 326,000-592,000 kwh of electricity annually. (Table 1, 2, the air-conditioning area is calculated as 16259 Sqm)

Table 1. Building Energy Monitoring of the Headquarters of China Merchants Property Development co.ltd (in 2011, Data reorganized from the China Merchants Property)

Project	Quantity		
Use area of all types of air-conditioning equipment (Sqm)	Unit A	Unit B	Unit C
	13180	2800	279
Total annual energy consumption of air conditioning (kwh)	790000		
Sub annual energy consumption of air conditioning (kwh)	620000	100000	70000
Sub annual unit energy consumption (kwh/ Sqm • y)	47.4	35.7	259.0
Annual unit energy consumption of air conditioning (kwh/ Sqm • y)	31.6		
Total annual energy consumption of the building(kwh)	1650000		
Annual energy consumption of unit construction area(kwh/ Sqm • y)	66.7		

Annotation: Unit A=Temperature and humidity independent unit
Unit B=VRV air conditioner
Unit C=Constant temperature and humidity unit

Table 2. Proportion of Passive Technology Contributed to Energy Saving (Data reorganized from the energy simulation calculation through DEST and DOE2, Lin Wusheng)

Project	Energy – saving contribution rate (%)	Sub Projects' saving rate relative to the proportion of the Total energy saving rate (%)
Envelope structure	12	18.2
Air conditioning	30	45.5
Natural ventilation	6	9.1
Electric lighting	16	24.2
Renewable Energy	2	3.0
Total	66	100

Annotation: rate (Passive methods) = rate (Envelope structure) + rate (Natural ventilation)

SUMMERY AND EXTENSION: PASSIVE TECHNOLOGY FOR ENERGY EFFICIENT RETROFIT OF EXISTING BUILDINGS IN HUMID YROPICAL AREA

Lingnan area has climatic characteristics similar to other hot and humid area. So the strategies can be applicable generally. Based on the study above, we make a summery and extension for passive technologies for energy efficient retrofit of existing buildings in humid tropical area on four levels:

1. Environmental level. Many elements of environment can be improved, such as the plants, water, ground pavement, etc. Adding or adjusting plants can help to wind-guide and sunshade. Grass brick, absorbent brick or planting ground, instead of concrete have better evaporation permeability, which contributes to regulating thermal comfort. Overheading the bottom of the surrounding buildings is effective to improve the environment ventilation. (Table 3)
2. Space organization level. Potentials for energy saving on this level can be excavated by space addition, subtraction and reorganization. Atrium and courtyard inserted into the existing space can improve ventilation and daylighting. Air-pulling shaft set up with existing staircase in high-rise buildings help to form the Venturi effect. Increasing of gray space like outdoor gallery and balconies is beneficial for ventilation and sunshading. Body ways such as over-handing, make conditions for self-shading. Size variation of the interior space can adjust indoor air pressure for air floating. Unnecessary partition walls that block wind flow should be taken away. (Table 4)
3. Material and structure level. Energy saving on this level mainly target on the building envelope. Various forms of sunshading can improve the comprehensive shading coefficient. Mosoon window is favourable for humid tropical area because of its excellent function for ventilation. Using energy saving glass for windows can improve insulation. Affixing ceramic tiles, coating with light-colored paint, adding green to the outer surface, or double skin wall can help to improve the heat transfer coefficient. Wind-guide wall added on outward can guide wind into the building. Adjusting the vents on outward interface help to make optimum ventilation and a homogeneous wind field. Water-storing roof, planting roof or shading on rooftop can reduce heat transfer. Skylight improves daylighting and ventilation both. Adding eco-epidermal to an existing building can strengthen its climate adaptability. (Table 5)
4. Use and management level. Space we use is not absolutely static. It can be adjusted to be better climate-adaptive. For instance, site the main space in the upwind sides, so to make good use of the windward, while the auxiliary space in the west as insulation layer. Open or close the atrium according to season to form chimney effect in summer and insulation effect in winter. Activity venue should be adjusted according to the comfort change of indoor and outdoor. (Table 6)

Table 3. Summarized Passive Retrofit Technologies on Environmental level.

Object	Instance	Schematic diagram	Major effect
Plant	Adding plants along the north side can help guide wind into the building	 Before / After	Ventilation
	Adjusting combination of the trees and shrubs can change the air path and guide wing into the building	 Before / After	Ventilation
	Planting deciduous trees in the direction of sunlight, would help shade solar radiation in summer but allow sunshine in winter	 Before / After	Sunshading

reserved elements　retrofit elements　water　wind　sunlight　heat

Refer to Table 3 (continued)

Object	Instance	Schematic diagram	Major effect
Water	Water arranged help to improve microclimate through evaporative cooling. Temperature difference that caused also benefits ventilation	 Before After	Cooling Ventilation
Ground material	Grass brick, absorbent brick or planting ground have good evaporation cooling permeability, which help to regulate thermal comfort	 Before After	Cooling
Surround-ing buildings	Increase overhead rate of the buildings' bottom is effective to improve environment ventilation	 Before After	Ventilation

Table 4. Summarized Passive Retrofit Technologies on Space organization level.

Object	Instance	Schematic diagram	Major effect
Atrium, Courtyard	Atrium and courtyard can be inserted into the existing space to improve ventilation and daylighting	 Before After	Ventilation Daylighting
Air-pulling shaft	In high-rise buildings, air-pulling shaft can be set up together with the existing staircases, so as to form the Venturi effect	 Before After	Ventilation
Gallery, Balcony	Increase of gray space such as outside gallery and balcony can form air pressure difference, that benefit ventilation and sunshading	 Before After	Ventilation Sunshading
Body	Use body ways such as overhanging to create condition for shape-shading and guide wind into the building	 Before After	Ventilation Sunshading
Transition space	Create size variations of the interior space that form indoor air pressure difference, which help to form wind fields for better air floating	 Before After	Ventilation
Partition wall	Unnecessary partition walls should be take away so as to make room for air flow	 Before After	Ventilation

reserved elements retrofit elements water → wind → sunlight → heat

Table 5. Summarized Passive Retrofit Technologies on Material and structure level.

Object	Instance	Schematic diagram	Major effect
Doors, Windows	Horizontal, vertical, comprehensive, baffle-style or shutter, etc. can be used to improve the comprehensive shading coefficient	 Before After	Sunshading
	Mosoon window is favourable for humid tropical area because its excellent function for ventilation	 Before After	Ventilation
	Use energy saving material for windows, such as coated, filmed, hollow, vacuum, heat-absorbing, painted, and photochromic grass, etc	 Before After	Insulation
Walls	Affixing ceramic tiles, coating with light-colored paint, green-wall, or double skin wall can improve the heat transfer coefficient	 Before After	Insulation
	Adding wind-guide wall besides the vents can be helpful to guide wind into the building	 Before After	Ventilation
	Vents layout on diagonal can make optimum ventilation and a homogeneous wind field indoor	 Before After	Ventilation
Roof	Planting roof, water-storing roof, shading framework on rooftop, etc. can reduce heat transfer greatly	 Before After	Insulation
	Oblique skylight, high-side window, roof skylight, etc. are useful for daylighting and ventilation	 Before After	Daylighting Ventilation
Epidermal	Adding eco-epidermal to an existing building can strong its climate adaptability	 Before After	Insulation Cooling

reserved elements retrofit elements water wind sunlight heat

Object	Instance	Schematic diagram		Major effect
Function planning	Site the main space in the upwind sides to make full use of the windward, while the auxiliary space in west, as an insulation layer	 Before	 After	Ventilation Insulation
Manually adjust	Open or close the atrium according to the season change, so as to form chimney effect in summer and insulation effect in winter	 Summer	 Winter	Ventilation Daylighting
Venue selection	Select activity venue according to comfort changes, e.g. arrange daytime activity indoor, while enjoy the breeze outdoor in the evening	 Daytime	 Evening	Ventilation Cooling

reserved elements retrofit elements water wind sunlight heat

Annotation: all the technologies showed on the tables 3-6 above just provide possibilities but not fixed pattern. We can make appropriate choices from the tables, according to the actual situation, such as the cost, feasibility or historic preservation, etc.

CONCLUSION

1. The paper summarizes the key points as sunshading, insulation, ventilation, cooling and daylighting to strengthen the buildings' climatic adaptability according to the climate and the thermal comfort in Lingnan area of China.

2. For the purpose of an understandable and practical design reference, the paper classifies the passive technologies for energy efficient retrofit of existing buildings in humid tropical area on four levels: environment, space organization, material and structure, use and management of the buildings.

3. Through a case study of energy efficient retrofit of the Headquarters of China Merchants Property Development co.ltd. The paper discusses the energy savings and economic benefits of energy efficient retrofit of existing buildings.

4. Further study may target on more specific methods for passive energy efficient retrofit of existing buildings and detail how they work, and how all the technologies react to the changing conditions of climate, social economic and the continues rapid advances in active technologies.

ABSTRACT

This essay proposes the necessity of natural ventilation of the hospital buildings in the hot and humid regions from the perspective of energy saving. It integrates the existing natural ventilation technologies from traditional houses and other types of buildings in such area to further investigate the natural ventilation design methods for the purposes of energy saving and requirements satisfaction, thus to provide useful data for the engineering design in the future.

KEY WORDS
Hot and Humid Regions, Hospital, Natural Ventilation, Passive Design

1. INTRODUCTION

In today's world, the energy issues which are drawn more attentions worldwide are generally recognized as one of the four survival prerequisites we are facing. It is estimated that the population will come to 10 billions by the end of this century,[1] resulting in more severe conditions of energy consumption.

The energy consumption of buildings has been taking a significant proportion in energy consumption of human life. According to the experiences from industrial developed countries, the building energy consumption took a ratio of 35% in total energy consumption.[2] In China, the building energy consumption holds 1/3 of total energy consumption and is still increasing.

Being different from normal civil buildings, the hospital building is a fairly complicated form in public architectural design field involving a lot of specialties, as there are too many types of energy required for hospital operation. Based on relevant data, the hospital energy consumption is 1.6-2 times than normal public buildings.[3] Nowadays, the hospital buildings in China in fact have faced with tremendous energy consumption pressure which drives us to focus on energy-saving researches. The energy-saving hospital is not only for reducing the operation cost of hospital, but also to lighten the burden of maintenance cost for medical services.

Sun Yinmin is a professor in School of Architecture, South China University of Technology, GuangZhou,China. Zhang Wenyu is a Ph.D Candidate in School of Architecture, South China University of Technology, GuangZhou,China. Zhang Chunyang is a professor in School of Architecture, South China University of Technology, GuangZhou,China.

2. NATURAL VENTILATION DESIGN FOR BUILDINGS IN HOT AND HUMID REGIONS

2.1. Climate features

The climate in the hot and humid regions features as high rainfall amount, high humidity and temperature, strong sunlight, and violent lightening. The humidity and temperature are stable all the year. The year-around temperature is about 27℃ with large amount of rainfall, while the humidity is 80%-90%, therefore, such regions are under hot and humid conditions all the year.

Such climate condition, existing in widely areas of China, is a combination of high temperature and high humidity. The energy consumption of the buildings under this kind of climate condition inevitably become a major issue to be solved if we aim to achieve absolute conformity and modernity of architecture.

2.2. Basic design principles of the buildings in hot and humid regions

Following factors must be taken into account for the buildings in hot and humid regions: heat protection, moisture proof and good ventilation in summer; but cold proof and heat preservation in winter are not necessary. Open design is preferred in overall planning, individual design and structure processing, making good use of natural wind; the building shall avoid a western exposure with sunshade; storm rain, flood, moisture and lightening proofs shall be seriously considered.

2.2.1. Heat protection

In hot and humid regions, the temperature in summer is very high and lasts so long that heat protection is the priority task for the buildings in this area. Amongst building shading is the most effective way to isolate the heat. Many shading methods are adopted for the hot and humid regions, from large cantilevered roof used in traditional houses, "Special shading method invented by Professor Xia Shichang" that is commonly used in Guangdong and Guangxi, to modern building shade. All are designed to reduce direct radiation from the sun onto the building, while using shading structure to improve ventilation performance for heat dissipation.

2.2.2. Moisture proof

Most hot and humid regions laid along the ocean or are located where rivers and lakes are spread over, so the relative humidity in such areas are greater than that in inlands. As a result, the adjustment of humidity in the building should be considered in addition to heat protection and temperature cooling. In particular at the end of spring and the beginning of summer, necessary measures shall be taken for moisture and mould proof of the building envelope, while reducing the effects of high temperature and humidity on human body and improving indoor comfort.

2.2.3. Ventilation

The climate characteristics of high temperature and high humidity in such area determine that the enclosing structure is not good enough to prevent solar radiation from into the room for the traditional buildings, ventilation shall be used for heat dissipation. Ventilation substantially is the flow of air, which is produced by pressure difference of air. The people living here learned a lot of experiences from their construction practices, so as to resist to those climate characteristics of high temperature, long duration, strong solar radiation and greater humidity.

3. NECESSITY OF VENTILATION FOR HOSPITAL BUILDING

Hospital building is high-energy consuming building and energy is used mainly for air condition and illumination. As a case study in Guangdong, electricity consumption of air condition is obviously seasonal, identical to the monthly electricity consumption of the hospital and the average temperature of Guangdong area. Its peak is from May to September, which is the hottest period, accounting for 50% of the total monthly electricity consumption. (Fig.1-3) In addition, the electricity consumption of air condition has a close relationship with the number of month using it. Hospitals with good natural ventilation can reduce or even cancel the use of air condition in transition season so that their annual electricity consumptions are lower, while hospitals with bad natural ventilation have to use air condition all year long which leads to a higher annual electricity consumption. (Fig.4) Electricity consumption of illumination remains the same without seasonal difference. Its difference is caused by the hospital size and the area using natural lighting only.

In summary, speaking of energy-saving of the hospital building, the energy consumption by air conditioner is the very first thing we need to discuss. If we adopt natural ventilation to reduce the burden of air conditioners, the operation costs of the hospital may be reduced as well as of the medical and health services, moreover, it provides high quality indoor air that is comfortable for the patients.

4. STUDY ON NATURAL VENTILATION DESIGN FOR HOSPITAL BUILDINGS IN HOT AND HUMID REGIONS

4.1. Natural ventilation by wind pressure

The wind pressure may be used as the main measure for implementation of natural ventilation in good wind environment. This kind of wind for ventilation by wind pressure is "Through Flow". According to the wind tunnel test: when the wind flows to the building, the positive pressure only will be generated on windward side of the building by blockage of the building. And, the negative pressure will be generated on appropriate places when the flow bypasses each side and the back of the building.The ventilation by wind pressure refers to such ventilation implemented by the pressure difference between the windward side and the leeward side of the building. The value of pressure difference is related to the form of building, the included angle of the building and the wind, and the ambient environment. When the wind flows to the front elevation in vertical way, the positive pressure at the center of windward side reaches to the maximum value, and the maximum negative pressure appears at the corner and ridge. (Fig. 5)

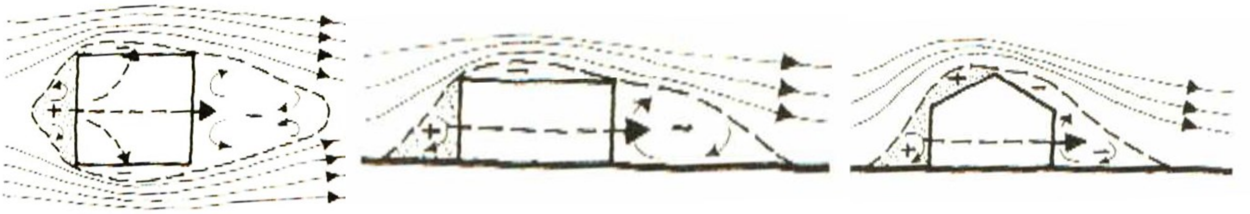

Figure 5 Principle of ventilation by wind pressure (Source: Allan Konya, Design primer for hot climates)

Another effect caused by wind pressure is the Venturi Effect. When the air flows, the flow rate will be accelerated because of shrinkage of space, thus the shrink section forms a negative pressure zone.

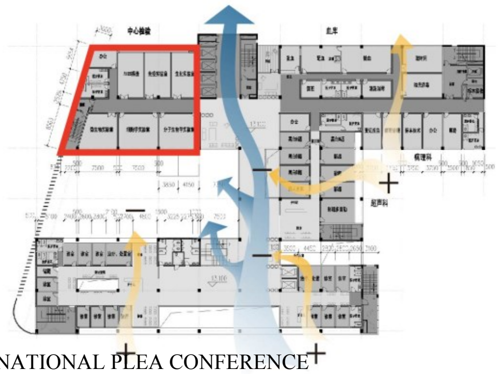
The layout suitable for such climate conditions in this area is that all rooms will be directly ventilated with goo d sunlight and the balconies or veranda shall be provided around the building. However, such space design is difficult for most of functional spaces in the hospital building. Therefore, all rooms in different position at each floor shall have ventilated air, and the through flow is required for plane design.

According to authors' experiences, there are two common strategies for hospital building design: 1. The air inlet of each functional area, as reasonable as possible, shall be placed in the dominant wind direction in summer time, without wind-shield wall, and the air outlet is placed on the other side. The inlet and outlet shall be aligned or displaced, so as to guide the air to flow into and circulate in the open plane from one side of the building. 2. Consecutive consulting rooms or wards in rows block the flowing air and shades the corridor space, therefore, the consulting room and ward shall not be arranged consecutively along the side of the building. It is recommended that some rest rooms or waiting rooms are designed in the middle of the corridor to leave the ventilation opening, so as to form through flow by wind pressure, thus to improve the ventilation performance of consulting room, ward and waiting space.(Fig. 6)

The waiting space and consulting room may be designed with courtyard concept, so that the wind can be flown into the room from the windows or holes on the building. When the courtyard window opens, the air may flow into the building for ventilation. (Fig. 7)

Secondly, take an example of bottom overhead method, which has seen more often in traditional building. The hospital building is designed to elevate the ground floor so as to improve slow flow on the ground floor and generate faster free-air speed in where is helpful for directing air flow. In addition, the air into the first floor will be in the building shadow by such overhead design, thus to reduce the air temperature and improve indoor thermal comfort. Except for some public rooms and necessary inspection rooms, the overhead design shall be available to the ground floor of hospital building as practicable as possible so that the internal building will have a better natural ventilation effect in the summer time and transitional seasons as well as a smoother process of thermal pressure ventilation. (Fig. 8)

Furthermore, the two ends of medical spaces shall not be closed, such as clinic and medical technology section, and open design is developed to generate positive and negative pressure difference at the opening of two ends of the building. Such opening is connected to the corridor, resulting in gathering and guidance of the outside air flow because of continuity of corridor, thus to improve indoor ventilation effect. The veranda assists wind guidance, also creates a comfortable zone with cool air due to shading effect, to some extent that the indoor comfort level will be increased.



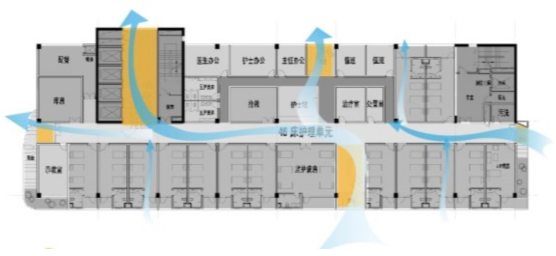


Figure 6 Schematic diagram of wind pressure ventilation in the hospital (source: capstone project by Zhong Haimin, directed by Zhang Chunyang)

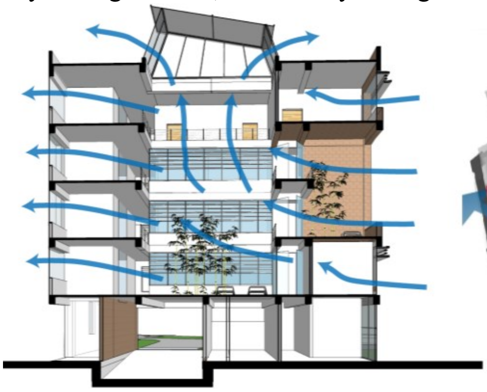

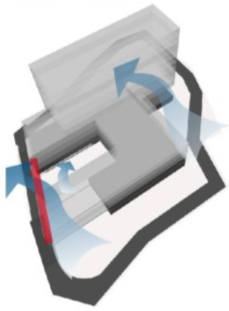

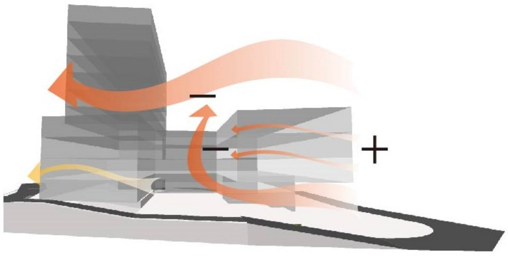

Figure 7 Schematic diagram of wind pressure ventilation in hospital courtyard (source: capstone project by Su Yanjie, directed by Zhang Chunyang)

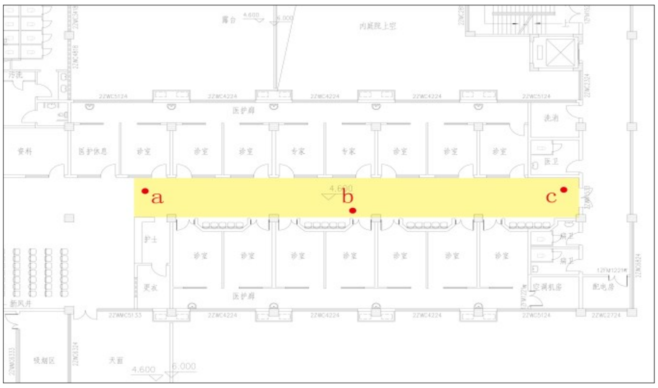
Figure 8 Schematic diagram of bottom overhead design for guidance of natural ventilation (source: capstone project by Zhong Haimin, directed by Zhang Chunyang)

From figure 9 to 12 are measuring analysis of ENT secondary waiting area of Panyu Central Hospital without air-conditioning, outdoor maximum temperature is 35℃ and minimum temperature is 27℃ in that day. It can be known from the data in figure, in waiting area there almost has lasting natural winds, whose speed is in the range of 0.1-1.0m/s. Since the outdoor temperature is too high, the erature and humidity in waiting area are not effectively reduced too much. Moreover, as the activities of patients, the humidity in middle of waiting area is higher than the other two test points. However, according to the interview, patients in waiting area do not feel discomfortable when they are in high temperature and humidity; on the contrary, the indoor environment with lasting natural winds make them feel more comfortable.



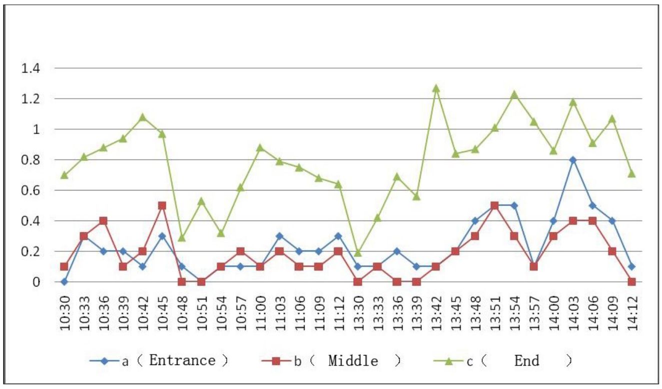


Figure 9 Measuring selected points of ENT waiting area in Panyu Central Hospital

Figure 10 Wind-speed comparison of ENT waiting area in Panyu Central Hospital

Figure 12 Humidity comparison of ENT waiting area of Panyu Central Hospital

(Fig.9-12 source: Huang Yinjing, Study of the Natural Ventilation Strategy of Hospital Clinic Waiting in Lingnan Regions [D].Guangzhou: Archives of South China University of Technology, 2012, directed by Zhang Chunyang)

Lastly, the ventilation by wind pressure also can be achieved by design of detail structures, in order to optimize the air quality in the room and improve thermal comfort degree.

Leading wind by sunvisor:

The sunvisor is widely used in the hot and humid regions. The building sunvisor is not only able to effectively resist solar radiation, but also to change the indoor ventilation performance by adjusting the form of sunvisor and the position in the enclosing structure to improve the indoor comfort, taking the position of wind entering into the room and airflow pattern into account. For example, the louvers may change the air flow upwards or downwards when the wind enters into the room; the horizontal sunvisor on the window may direct the air flow upwards; the gap between the horizontal sunvisor and the wall may direct the air flow downwards; when the louvers are fully opened, the wind in wider area may be flown into the room. (Fig. 13)

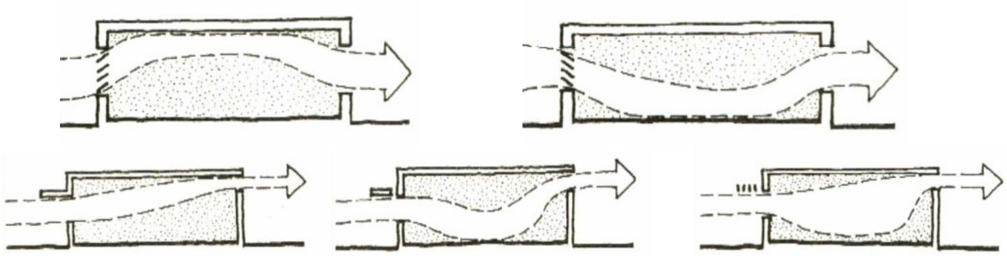

Figure 13 Leading wind by sunvisor (Source: Allan Konya, Design primer for hot climates)

Options for window opening:

Normally, these windows with greater opening and ventilation areas are selected for the hospital building. Opening out by casement window is commonly adopted because of good ventilation and greater opening areas. In case of a higher numbers of opening windows and narrow average width of opening window, the vertical hung window can be fully opened and reaches the maximum ventilation rate with air leading effect, so it is recommend as well. The doctor offices, as auxiliary function of the hospital, are always located in west-east direction, the louver (i.e. vertical hung window) is preferred to meet the requirement of wider ventilation area and direct air flow in the summer time and transitional seasons for the purposes of sun-shading and air leading effect.

In order to improve indoor ventilation performance, it is suggested that the upper ventilation window shall be set up on the partition in the corridor and ventilation louver is provided on the doorstop to reduce hot air circulation.

4.2. Natural ventilation by thermal pressure

Another principle for natural ventilation is the thermal pressure difference generated by the air inside the building, which is so called “Chimney Effect”. The thermal pressure difference in the building, namely, “Chimney Effect”, can be used to achieve natural ventilation for the buildings which are affected by the layout of surrounding buildings and tall plants. According to the principle of rise of hot air, the dirty hot air is vented out from the upper air outlet, and the outside fresh cold air is sucked from the building bottom, in order to implement natural ventilation. In building design, the vertical chambers, like stair well and atrium shall be designed to meet the elevation difference of air inlet and outlet. The higher the temperature difference of inside and outside temperatures and elevation difference of air inlet and outlet, the more obvious the thermal pressure effect. Being different from natural ventilation by wind pressure, the ventilation by thermal pressure is more suitable to the ever-changing and adversely outside wind environment.

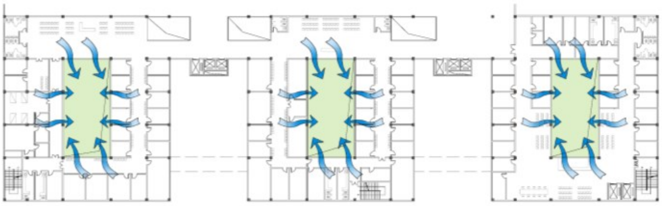
The courtyard may be designed for the hospital building in the hot and humid regions. The courtyard is one of well-known characteristics for Chinese residence. In the hot and humid regions, the traditional residences use such structure to create a good indoor ventilation condition. The courtyard design for the hospital building reflects the thermal pressure effect used by theses residences in the hot and humid regions, so as to improve the natural ventilation performance.

1. Light roof prolongs from the surface and open a window on the side of prolonged section as the air outlet, utilize and heat the accumulated air. Under heat pressure drive, the airflow is inhaled from the windows at each floor and then vent out after rise, thus to strengthen the chimney effect of the courtyard, and use the thermal pressure to provide side ventilation for the courtyard. (Fig. 14)

2. Set up exhaust chimney and increase height of air outlet, add the elevation difference of air inlet and outlet and the thermal difference of the air in the courtyard, and improve the natural ventilation by thermal pressure.

3. Combine the courtyard design to set up an integrated ventilation channel, use the courtyard space as the ecological exchange space, conduct overall design on building structure layer and courtyard space, and create an integrated ventilation channel to facilitate the natural ventilation of hospital building.

4. Set up pitched skylight to catch the wind on the windward side, and bring the outside natural wind into the courtyard to form natural ventilation; utilize the wind pressure difference of front and back of the pitched skylight on the leeside to draft the indoor air for coordination of courtyard ventilation.



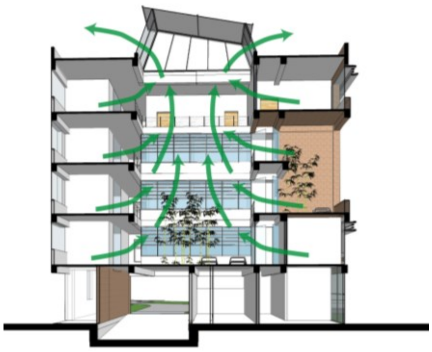


Figure 14 Schematic diagram of thermal pressure ventilation in the hospital (source: drawn by the author and capstone project by Su Yanjie, directed by Zhang Chunyang)

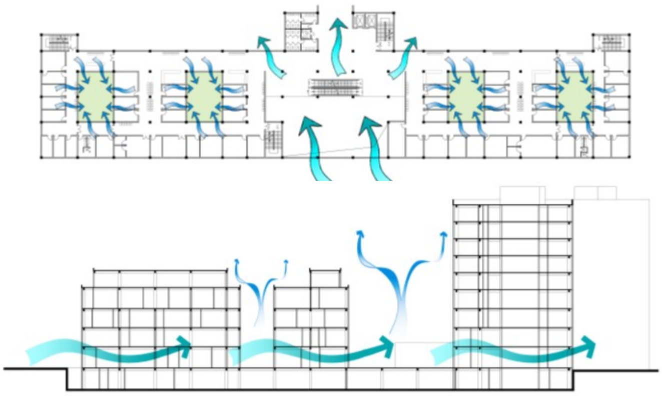
4.3. Combination of wind pressure and thermal pressure for natural ventilation

Due to the building is subject to the weather conditions, geographic location, ambient environment and building layout, the natural ventilation design is normally combined by wind pressure and thermal pressure in practical application. The wind pressure and thermal pressure play different roles. In the less deep sections, the wind pressure is prevail for ventilation, while in the deeper sections, the ventilation by thermal pressure is adopted. (Fig. 15)

Taking the Shenzhen Binhai Hospital as an example. There are air vents provided at the front and back of the hospital street so that wind pressure ventilation will be achieved. In addition, the top of hospital street has an elevated roof to provide a good lighting condition without direct radiation from the sunlight. Therefore, the whole elevated roof forms the ventilation by thermal pressure and eliminates the hot air on the top as well. As mentioned above, the Shenzhen Binhai Hospital is able to implement the ideal natural ventilation by combining the wind pressure and thermal pressure, thus to significantly reduce the energy consumption. (Fig. 16)



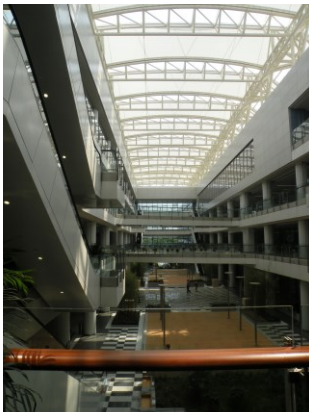


Figure 15 Combination of wind pressure ventilation and thermal pressure ventilation (source: drawn by the author)

Figure 16 Hospital street of Shenzhen Binhai Hospital (source: photographed by author)

4.4. Assisted mechanical ventilation

In some large-scale buildings, due to longer ventilation path and greater flow resistance, the natural ventilation hardly can be achieved only by wind pressure and thermal pressure. For those cities with serious air pollution and noise pollution, the direct natural ventilation will be harmful for human health when it brings the awful air and noise into the house. In this case, the assisted mechanical ventilation system is usually adopted. This system has a full set of air circulation channels, supplementing by some air treatment methods satisfying the ecological concepts (for example, soil pre-cool, pre-heat, heat exchange of deep well water, and it facilitates indoor ventilation by certain mechanical means. Comparing with fully natural ventilation, the mechanical plant with auxiliary power may consume a certain volume of energy, but this system is able to re-organize the air flow to achieve a better performance of natural ventilation.

The roof of hospital street of Guangdong Panyu Central Hospital is designed to a ventilated roof. The assisting mechanical ventilation plants, water curtains, are provided at the two sides of the roof, in order to reduce the temperature of hospital street and purify the air quality for natural ventilation. (Fig. 17)

5. CONCLUSION

The air conditioners used for hospital building in the hot and humid regions have enormous energy consumption. This essay discusses about the design strategies of hospital building in the hot and humid regions from the perspective of energy saving, and makes a contribution for constructing a energy-saving and adequate hospital building.

ABSTRACT

Engineering design is a process to find the best solution to satisfy various design criteria. This work aims to optimize the glazing façade perfomance and the window size by minimizing the heating, cooling and electric lighting demand of office buildings. Accordingly, this paper presents a comprehensive analysis in order to study the balance between daylighting benefits and energy requirements in perimeter office spaces taking into account glazing properties control with window size, orientation and climatic conditions. The glazing area and thermophysical properties of the window were taken as the main variables. The optimization was carried out by using a combination of Energyplus7.0.0 and GenOpt softwares. The energy consumption can significantly change affected by geometric parameters, materials properties and types of window glass, orientation and climatic conditions. Optimum range of each parameter was calculated in order to minimize annual energy consumption with a hybrid multidimensional optimization algorithm: GPSPSOCCHJ algorithm. Furthermore, since the annual energy consumption effectively depends on the type of air conditioning system, the optimization process was carried out individually with both evaporative cooling system and compression cooling system. The results indicated that using the evaporative cooling system compared is more appropriate and economical in comparison with the compression cooling system. Also, investigations indicated that reflective double glass and low-e double glazed with argon layer glass is appropriate for Tehran office building and can respectively allocate the maximum level of window area and the minimum of energy consumption.

Keywords: Glazing façade, Optimization, GPSPSOCCHJ optimization algorithm, Energy consumption

INTRUDUCTION

Window is considered as one of the most important components influencing the thermal performance of buildings. Their shape, size, optical and thermal properties, orientation and shading/daylighting attachments determine the interior daylighting conditions as well as the visual and thermal comfort for the occupants. The balance between daylight provision and reduction in energy consumption or demand through appropriate control of solar has been investigated in a few studies by several researchers (Lee et al., 1995; Citherlet et al., 2001; Franzetti et al., 2004; Hviid et al., 2008; Tzempelikos et al., 2010). Coupling between daylighting and thermal simulation is necessary for a comprehensive analysis. In 1998, Clarke et al. compared the annual energy consumption of three different types of glazing system using ESP-r and found reductions of about 4.5%, 10.9% and 6% in maximum heating capacity, maximum cooling capacity and total energy consumption respectively.

Optimized glass facade design may improve exploitation of daylight and result in significant savings in electricity consumption for lighting. Reinhart (2002) calculated the daylight availability for several Canadian locations considering the effects of climate, external shading, facade orientation, glazing type and occupancy schedules. The study showed that location, orientation and blind slat angle all have a significant impact on daylight autonomy while external objects and glazing type were less important. Optimized glass facade design may improve exploitation of daylight and result in significant savings in electricity consumption for lighting. Reinhart (2002) calculated the daylight availability for several Canadian locations considering the effects of climate, external shading, facade orientation, glazing type and occupancy schedules. The study showed that location, orientation and blind slat angle all have a significant impact on daylight autonomy while external objects and glazing type were less important.

The sophisticated characterizations of window and shading systems sparked a large amount of studies on this topic (Reinhart and Walkenhorst, 2001; Walkenhorst et al., 2002; Robinson and Stone, 2006; Loutzenhiser et al., 2007), and various calculation models that predict illuminance on the interior surfaces of a building as well as on the work plane level are available (Mardaljevic, 2001; Fakra et al., 2011). The different models have some limitations; for example, some models use constant glass transmittance, some others use limited evaluation metrics such as daylight factors (Ghisi and Tinker, 2005); and some have limitation in sky luminance inputs. Moreover, it is complicated to modify existing software codes to adapt specific necessities or to present results using different measures. As to the latter, advanced daylighting metrics may be properly used in daylight performance evaluation (Nabil and Mardaljevic, 2006; Reinhart et al., 2006). Finally, the significant computational time, the complex calculation procedure and the inability to interpret simulation results are all factors preventing the design community from picking up the advanced design analysis schemes with very few exceptions (Reinhart and Wienold, 2011).

This study has been tried to optimize the window size and glass type with the objective of minimization of annual energy consumption function. In such a way, while reducing energy consumption, occupants' thermal comfort and the brightness level of each space remain in the acceptable range. For this purpose the modeling of thermal and visual performance of building's transparent façade is performed by EnergyPlus software and the results are optimized by GenOpt software and GPSPSOCCHJ algorithm and the effect of all parameters among solar heat gain coefficient (SHGC), thermal transmittance of window (U_{value}), and visual transmittance is considered. Finally, calculations and evaluations will lead to provide window design recommendations due to climate.

METHODS

In this paper, as shown in **Figure 1**, a case room is considered in accordance with the case No. 600 in ASHRAE 140 standard. Accordingly, this sample space is an office with the dimensions $6 \times 8 \times 2.7\ m^3$ in the middle of a tall building which only a wall with 8m width and 2.7m height is in contact with outdoor climatic conditions of Tehran. According to **Table1** the wall adjacent to the outdoor, specified by common materials for office buildings that respectively from in to out includes veneer plaster, insulation, concrete block, stucco and stone.

Table 1. The wall adjacent to the outdoor construction

field	units	obj1	obj2	obj3	obj4	obj5
name		stone	25mm stucco	concrete block	50mm insulation	plaster(light)
roughness		medium rough	Smooth	medium rough	medium rough	medium smooth
thickness	m	0.03	0.0254	0.2	0.0508	0.01
conductivity	W/m.K	3.17	0.72	0.33	0.03	0.16
density	kg/m³	2560	1856	1380	43	600
specific heat	J/kg.K	790	840	880	1210	1000

As shown in **Table2**, eight types of window glass have been considered: 6mm clear single glazed, clear double glazed with argon layer, clear double glazed with air layer, low-e clear single glazed, reflective clear single glazed, low-e clear double glazed with argon layer, low-e clear double glazed with air layer, reflective clear double glazed with air layer. Dimming of overhead electric lighting is determined from interior daylight illuminance calculated at one or two reference points. Two reference points in coordinates 3×1.6×1 m^3 and 3×6.4×1 m^3 toward the wall adjacent to the outdoor are considered as lighting evaluation criterion. Also, in order to simulate the thermal and lighting energy demands, the EnergyPlus software is used.

Table2. Types of window glazing construction

Field	Obj1	Obj2	Obj3	Obj4	Obj5	Obj6	Obj7	Obj8
Name	6mm clear single glazed	clear double glazed with argon layer	clear double glazed with air layer	low-e clear single glazed	reflective clear single glazed	low-e clear double glazed with argon layer	low-e clear double glazed with air layer	reflective clear double glazed with air layer
Outside layer	Clear 6mm	Clear 3mm	Clear 3mm	PYR B clear 6mm	REF a clear mid 6mm	PYR B clear 6mm	PYR B clear 6mm	REF a clear mid 6mm
Layer2		Argon 13mm	Air 13mm			Argon 13mm	Air 13mm	Argon 13mm
Layer3		Clear 6mm	Clear 6mm			Clear 6mm	Clear 6mm	Clear 6mm

EnergyPlus is one of the most comprehensive whole-building energy simulation tools that are capable of modeling several features including solar irradiance and illuminance under different sky conditions, advanced fenestration systems, blind controls, indoor illuminance maps, lamp controls, and heating/cooling energy impact associated with daylighting controls (Seo et al., 2011). Building model, location and Climatic conditions design in Software environment. EnergyPlus weatherdata file is used for energy performance calculations and indoor climate analysis. Hourly based outdoor climate data (dry-bulb air temperature, relative humidity, wind speed, direct solar radiation and diffuse radiation on horizontal surfaces for 8784 hours) was used to create the model for calculation. Comparability of current study results for other climatic areas can be done through monthly and yearly average parameters which are indicated in **Table3** (Hanni.al et al., 2012).

Table 3. Reference year parameters

Month	Air temperature ˚C	Relative humidity %	Wind speed m/s	Direct solar radiation Wh/m2	Diffuse radiation Wh/m2

By Considering Constraints that describe below the building annual energy consumption with a focus on providing residents thermal comfort is calculated by EnergyPlus.

1. $-0.5 \leq PMV \leq 0.5$
2. The minimum illuminance required by international standards on the desk: 500 Lux
3. Heat generated within the space caused by a computer, printer and other accessories available: 800 W
4. Number of people: 4
5. Hours due to the discontinuous use: 7:00 to16:00
6. People with the metabolic rate of 100 W while seated
7. People Clothing thermal resistance, 0.6, 0.5, 0.7, 0.9 clo respectively for spring, summer, autumn and winter conditions.
8. Constant heating set point: 23.5˚C
9. Constant cooling set point: 26˚C
10. Internal gains for lights: Lighting level calculation method is used to create the maximum amount of lights to this set of attribute choices : 400 W

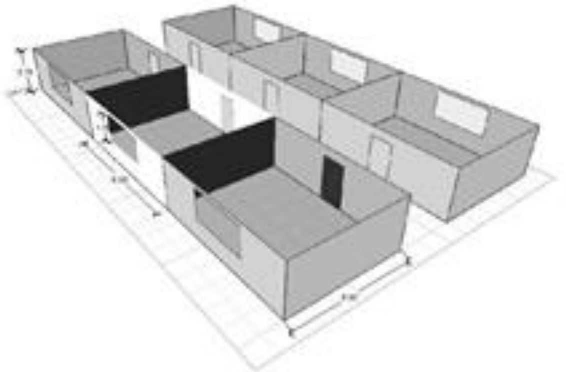

Figure 1 *Office space in the initial position study*

A key part of using optimization tools with artificial intelligence-based algorithms for optimal design is defining an appropriate objective function and constraints. In the issue examined in this article inside light level, inside temperature, sunshade dimensions, wall thermal resistance, energy consumption In order to provide lighting, heating and cooling, All are measurable quantities that can be offered based on the objective function and constraints. On the other hand, the purpose of this study was the amount of illuminanace inside the building and its thermal behavior which is obtained by minimizing the building's annual energy consumption influenced by the optimal size of the window and its different types. For daylighting control types available in EnergyPlus, optimization algorithms must support discrete (on-off or 2 or 3 steps controls) and continuous (dimming control) variables. In addition, the selected algorithm should support intrinsic approximation problems. Detailed buildings energy simulation tools such as EnergyPlus, TRNSYS, and DOE-2 involve solving a series of systems of partial and ordinary differential equations that are coupled to algebraic equations. Therefore, an optimal solution for a continuous cost function may be difficult to obtain without using a heuristic approach (Wetter et al., 2003). Wetter (2008) recommends hybrid algorithms using the General Pattern Search (GPS) method coupled with the HookeeJeeves algorithm with multiple starting points or the Particle Swarm Optimization (PSO) algorithm. Using this algorithm in GenOpt, with Energyplus output as input of the optimization problem, can be found to answer issue.

As previously noted, the objective function of this issue is the total annual energy consumption which is minimized by determining the coefficients for the efficiency and production cost of the energy. The above issue is optimized and analyzed for two efficiency, compression cooling system and evaporative cooling system in Tehran climate.

RESULTS

Order to determine and Analyzed the optimum dimensions of the window at the four main directions, for 8 types of glass studied by using either compression or evaporative cooling system, after performing optimization for 64-state results were as follows. **Figures 2, 3, 4 and 5** show the optimal window area respectively for the North, South, East and West orientations, for evaporative cooling system in comparison with compression cooling system. As can be seen, the use of evaporative cooling system in the same condition the optimum window size will be larger in all four directions. According to **Figure 2**, in the north, reflective double glass in both cases is an option and its size in evaporative cooling system is $4.5\times2.25\ m^2$ (47% of surface) and in compression cooling system is $4\times2\ m^2$ (37% of surface). As shown in **Figure 3** in the south, reflective double glass is the best and its optimum size in evaporative cooling system is $5\times2.5\ m^2$ (58% of surface) and in compression cooling system is $4.31\times2.15\ m^2$ (43% of surface).

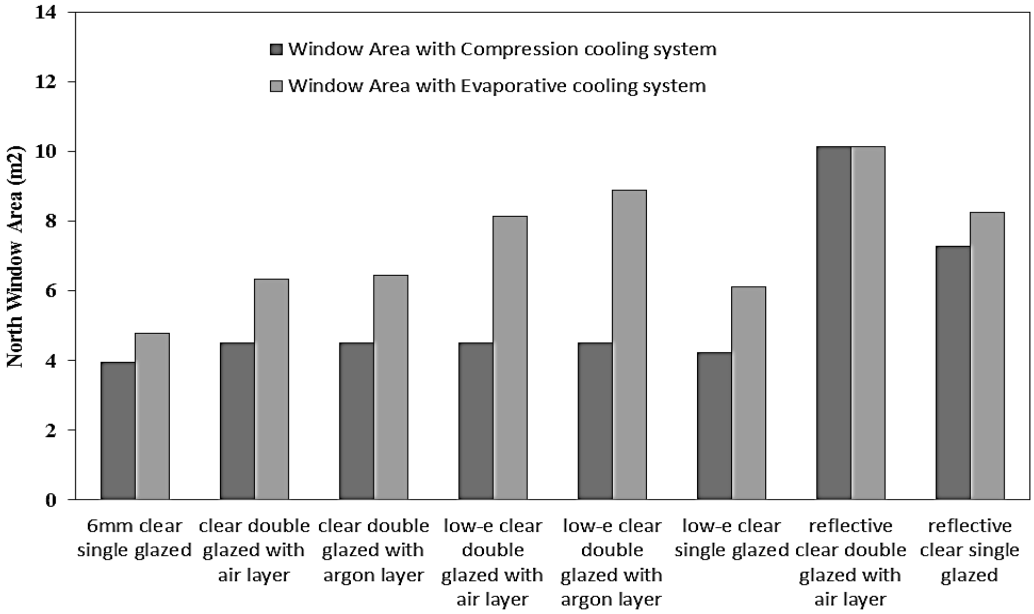

Figure 2 *Comparison of optimal window sizes for eight types in North, for systems, evaporative cooling and compression cooling*

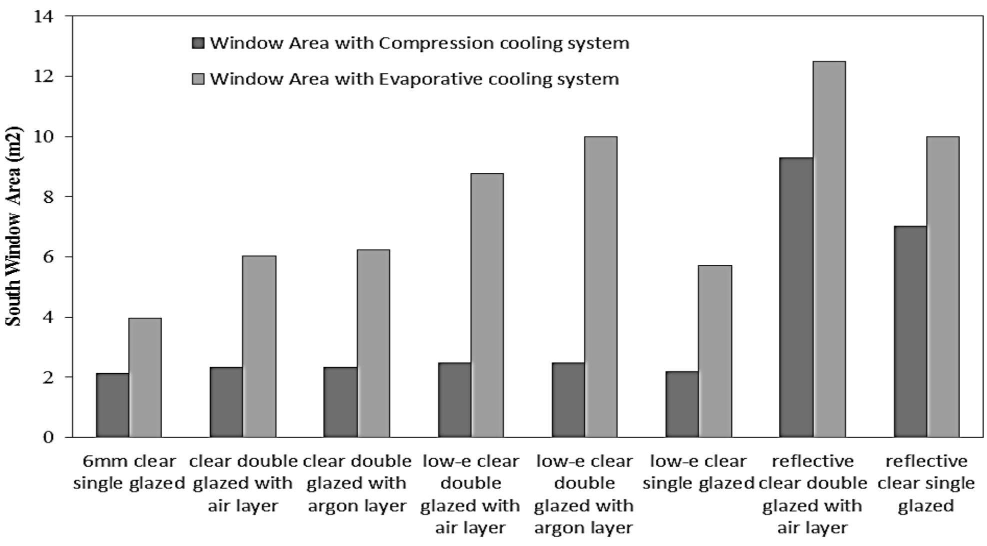

Figure 3 *Comparison of optimal window sizes for eight types in South, for systems, evaporative cooling and compression cooling*

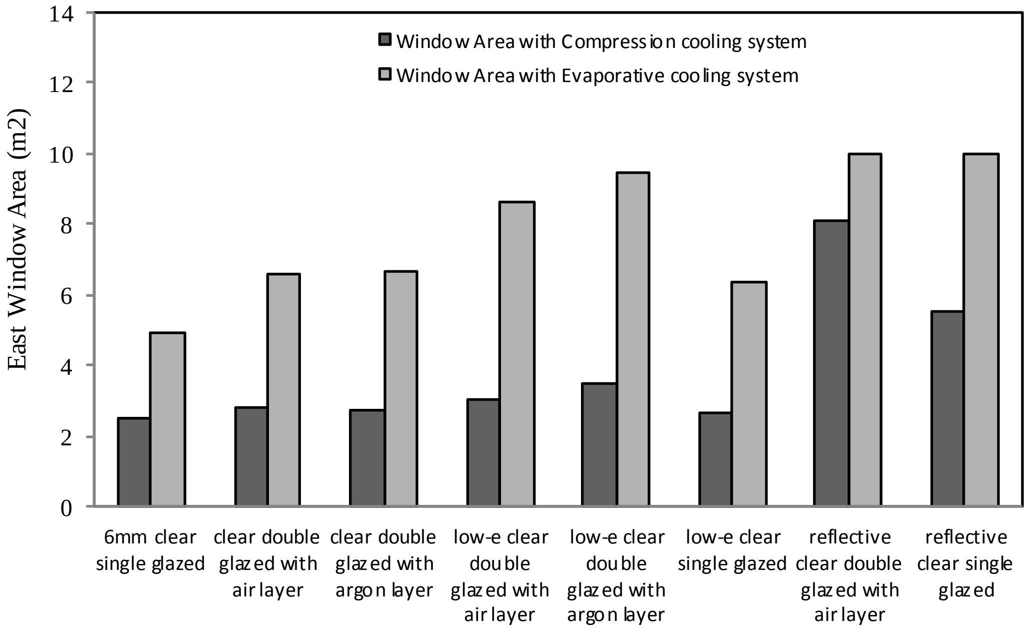

Figure 4 *Comparison of optimal window sizes for eight types in East, for systems, evaporative cooling and compression cooling*

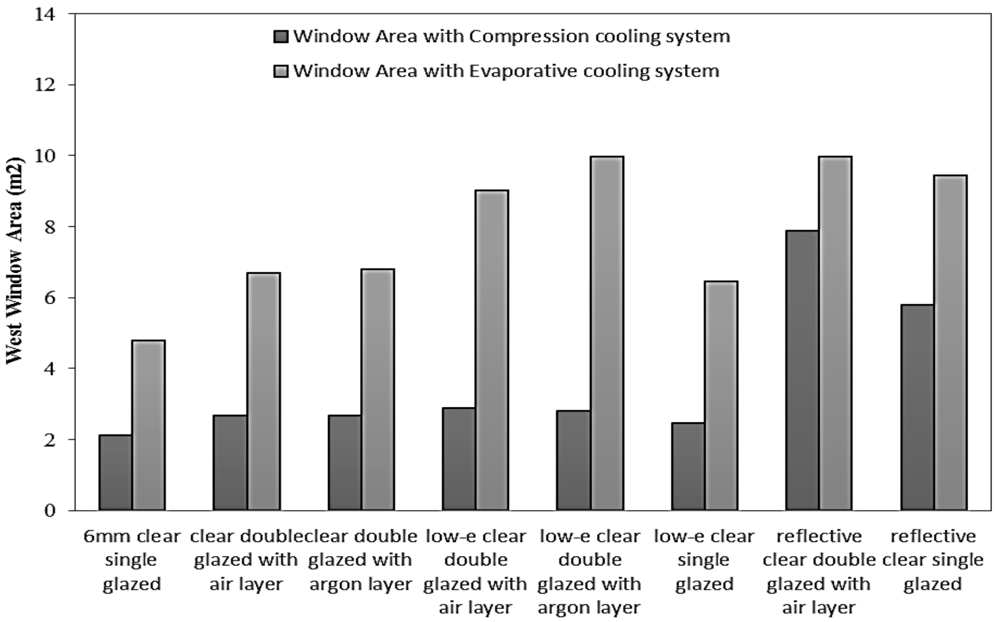

Figure 5 *Comparison of optimal window sizes for eight types in West, for systems, evaporative cooling and compression cooling*

Data in **Figure 4** indicate that East is a good choice for reflective double glass and the dimensions of evaporative cooling system is 2.23×4.46 m^2 (46% surface) and of compression cooling system is 4×2 m^2 (37% of surface). As well as shown in **Figure 5** in west direction, If using compression cooling system reflective double glass, and if using evaporative cooling system Low-emissivity double glass with argon layer and reflective double glass are better choice and Their dimensions are respectively 1.98 × 3.96 m^2 (36% surface) in compression cooling system and 2.23 × 4.46 m^2 (46% surface) for both glasses in evaporative cooling system.

The **Figure 6** shows that the optimum surface area for eight types of glass windows in the four cardinal directions, by using Evaporative cooling system instead of compression cooling system, increases in various glasses from 13 to 300 percent. As seen in **Figure 6**, using an evaporative cooling system the window size can be significantly increased with the objective to minimize the energy consumption. Among this low-emissivity double glass with argon layer with more than 300% increase in the south had the highest and reflective double glass with air layer with up to 34%, had the lowest increase. This difference is due to the Low-emissivity double glass is greater than reflective double glass amount of solar energy.

Also, **Figures 7 and 8** show the window optimum area for eight types of glasses in four different directions with each of the desired cooling system. It is observed that with evaporative cooling system, the optimum amount of window area in the south is higher than the other main directions and the area of reflective Double glazed window in both systems is higher than the other window.

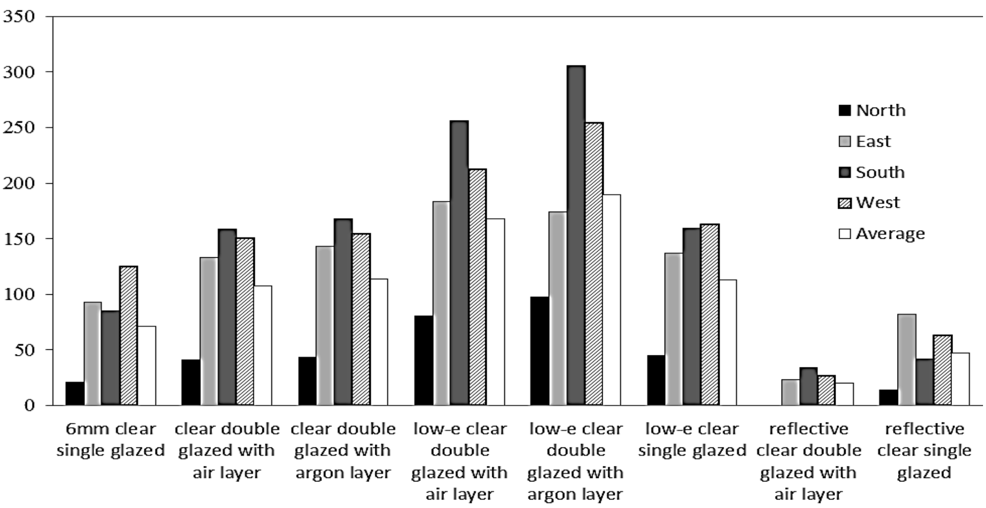

Figure 6 *Percent increase in the optimal value of the window area for eight types in four directions, for use of the evaporative cooling system for comparing compression cooling system*

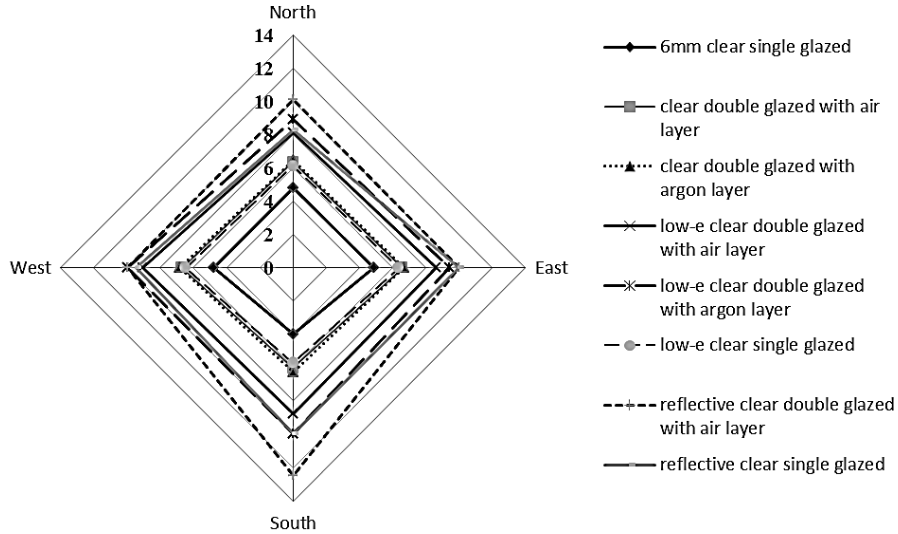

Figure 7 *The optimal value of the window for the evaporative cooling system efficiency*

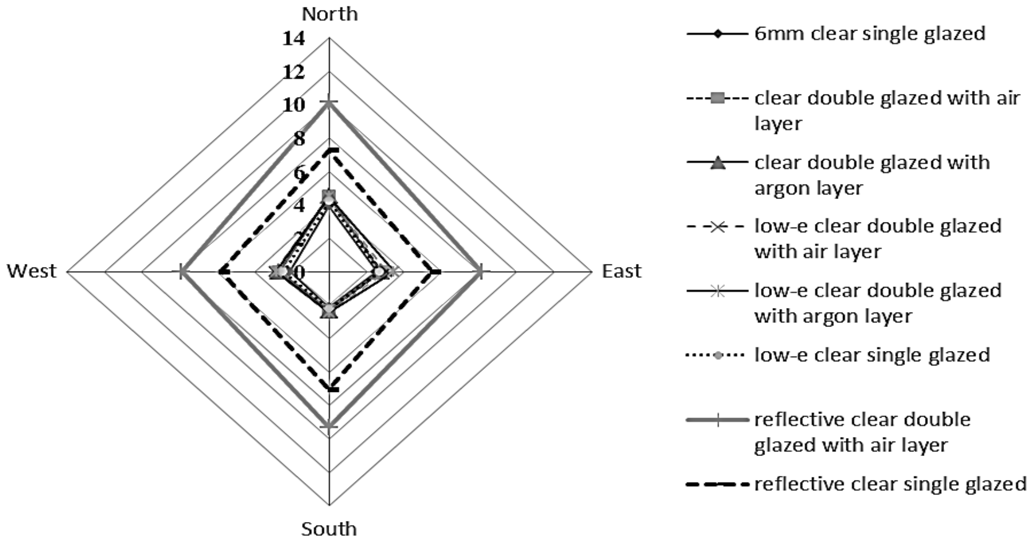

Figure 8 *The optimal value of the window for the compression cooling system efficiency*

DISCUSSION AND CONCLUSION

In this study, the effects of location, material and size of the windows were investigated in order to minimize the annual energy consumption of administrative units with emphasis on the effect of fenestration surface. The results indicate that using the evaporative cooling system compared to compression cooling system is more appropriate and more economical in Tehran climate and if office window has been placed in the optimum orientation, glass area can allocate up to 50% of façade surface. Also, reflective double glass and low-e double glazed with argon layer glass are appropriate for Tehran office building units and can respectively allocate the maximum level of window area and the minimum of energy consumption. Moreover, in the same conditions, using the evaporative cooling system, window optimum size in the four main directions can be varied from 19% for single-glazed window to 58% for reflective double-glazed window in the South direction.

ABSTRACT

This research aims to develop a dry assembly, easy to build, flexible and reversible constructive system for the building of energy efficient (temporary) schools located in different climate conditions. With the intent to build schools characterized by good spatial and technological quality, high level of indoor comfort and low energy consumption it was necessary to develop an extremely simple (but at the same time extremely versatile) constructive system, able to easily adapt to different design, environmental and energy strategies. The developed system uses cross laminated timber and other natural materials and consists of small and light modular elements that can be quickly assembled according to different configurations.

Spatial-functional, technological-constructive and energy-environmental performance of the developed system have been evaluated, tested and optimized in an intense "try and test" phase in different climate zones: cold (Helsinki, Finland), temperate (Rome, Italy) and hot (Nairobi, Kenya).

In particular, the spatial-functional quality was evaluated by the application of the system in several different design configurations of kindergartens optimized with respect to following parameters: type of teaching activity, age and needs of users, spaces functionality and flexibility, paths and relationships between different (indoor and outdoor) spaces and multifunctionality of the common areas.

In relation to technological-constructive performance particular emphasis has been given to: rapidity and simplicity of assembly of building elements, expandability and modifiability of the building in response to the changing needs, cost and simplicity of maintenance over time and use of natural and low environmental impact materials.

To reduce the annual energy consumption (for heating, cooling and lighting) different active and passive environmental strategies and devices have been developed for the three different chosen climatic zones. The level of hydrothermal, acoustic and visual indoor comfort has been evaluated and quantified with the support of thermodynamic simulations and the annual energy demand was also calculated and optimized trough appropriate software.

In conclusion, tests (design application and simulations) conducted in this research have shown that the developed reversible constructive system (applicable in temporary schools) combines good spatial-functional and technological-constructive qualities with a high level of indoor comfort and a low energy consumption. Moreover, the system resulted extremely efficient also in very different climatic conditions, thanks to its easy adaptability to different configurations and strategies.

INTRODUCTION

Building - high quality and low energy consumption - schools (particularly kindergartens) are a priority of the many governments in the world. In Italy, e.g., more than 50% of school buildings do not correspond to current spatial, functional, energy and seismic standards and urgently need to be renovated, expanded or replaced. In some regions of Germany it is an urgent need to build many kindergartens to ensure every child a place to spend the day while its parents work. Even in most developing countries (Africa and Southeast Asia) the humanitarian interventions are focusing their field of action on the creation of schools: e.g. Zambia needs immediately 10,000 classrooms. Moreover, in many countries, there is also the need to provide temporary school buildings (quickly realizable and totally removable) to be used after natural disasters or during the redevelopment of existing schools.
Furthermore, an investigation carried out a few years ago by the U.S. Green Building Council (USGBC) has estimated that in the U.S. "*more than 55 million students spend hours every day in buildings with poor ventilation, inadequate lighting, inferior acoustics and antiquated heating systems*" (www.usgbc.org). Because of this, USGBC started a study called "Greening America's Schools - Costs and benefits" which concluded that *"Greening school design provides an extraordinary cost-effective way to enhance student learning, reduce health and operational costs and, ultimately, increase school quality and competitiveness"* (Kat, 2006). Based on these research results and with the aim of promoting the development of energy-efficient schools, 2006, USGBC launched LEED for schools. These new suite of rating systems recognizes the unique nature and educational aspects of the design and construction of schools. Also the U.S. Department of Energy has promoted a program called *"EnergySmart Schools"* that shares "*best practice and technologies for achieving significant savings in both new construction and school renovation*". This program also provides tools and training for school planning, financing, operation & maintenance, and energy education. Moreover, the ASHRAE has just published an *"Advanced Energy Design Guide for K-12 School Buildings"*.

OBJECTIVES AND METHODOLOGY

On the basis of the above considerations this research aims to develop an easy to build, flexible and reversible constructive system for the building of high spatial-functional quality, good technological-constructive standard and excellent energy efficient school buildings located in different climates. The idea of designing buildings in different climatic conditions was born from a faculty exchange between UNICAM, Italy and Cal Poly, USA in which 2nd year architecture students have been involved in the design of energy-efficient school buildings located in different climatic zones in Italy and in USA (Rossi, 2012). Based on this very positive didactic experience it was decided to accept "the challenge" of designing in different climatic conditions also for this research, particularly for the design of a very versatile constructive system.

To achieve this goal, the research has been organized into the following phases:

1) Detailed analysis of: A) spatial, functional, energy and seismic standards for school buildings in different countries, B) types of learning and teaching and their impact on the design of the spaces, C) materials and constructive systems with lower environmental impact and suitable for use in reversible processes, D) Climatic conditions and indoor comfort standards in three cities chosen as case studies, E) passive and active energy strategies and devices efficient in different climate.
2) Development of a constructive system in cross laminated timber.
3) "Try and test" of the spatial-functional, technological-constructive and energy-environmental performance of the developed constructive system in different climate through appropriate tools.
4) Optimization of the constructive system on the basis of the results of the "try and test" phase and development of the final system.
5) Application of the system in 3 case studies: Helsinki-Finland, Rome-Italy and Nairobi-Kenya.
6) Evaluation of results of applications.

DEVELOPMENT OF A CONSTRUCTIVE SYSTEM FOR SCHOOL BUILDINGS

With the intent to develop a constructive system for the building of energy efficient (temporary) schools located in different climatic conditions, particular importance has been given to achieving a high level in three categories of performance: spatial-functional, technological-constructive and energy-environmental. In this paper, for reasons of space and in relation to the topics of the conference, more emphasis is given to the last one.

Spatial-functional performance

In school buildings the type of teaching and the specific needs strongly influence the spatial-functional aspects (Dudek, 2007). At the same time the architecture (as consequence of the spatial-functional choices) plays an extremely important role: it houses not only the spaces in which it is possible to perform a certain function but, if well and smartly designed, it is able to improve the way and the efficiency in performing this function. The Dutch architect Herman Hertzberger, who has more than 50 years experience in design and construction of all kinds of school buildings, believes that in school buildings "*architects should […] create spatial conditions that will benefit learning in general sense. The building should provide a general framework for education and learning, while being flexible enough to respond to changing demands […]. Schools are where you can withdraw and adopt a position with respect to others, where you learn to assume a place in society*".

Because of this, kindergartens designed in this research aim to be designed "as a city" and at the same time "as a home" (Hertzberger, 2009). "As a city": with public and private spaces, "squares" to meet other students, enough playgrounds, visual links and a "streets" system. "As a home": where children don't feel lost and have a sense of security. Between the many possible spatial-functional configurations, three (based on different teaching concepts and adequate to the different climatic conditions typical for the specific case study) are chosen: 1) *compact*: with a big indoor collective space as middle point and short connection ways between the different rooms, suitable for an "open concept" of kindergarten, where kids of different ages are free to move between the various spaces - recommended for cold climate; 2) *linear*: with a bigger distance between the different rooms and more open to the outdoor space, suitable for a "classical concept" of kindergarten, where kids of different ages play in different rooms - recommended for temperate climate; 3) *courtyard:* with a big covered outdoor collective space as middle point, suitable for a "outdoor concept" of kindergarten, where kids spend a lot of time a day outdoor - recommended for hot climate (see fig. 1).

All configurations include some standard spaces (see caption of fig. 1) characterized by a careful study of surface color - which can be aggregated in different ways, based on different teaching concepts or climate conditions.

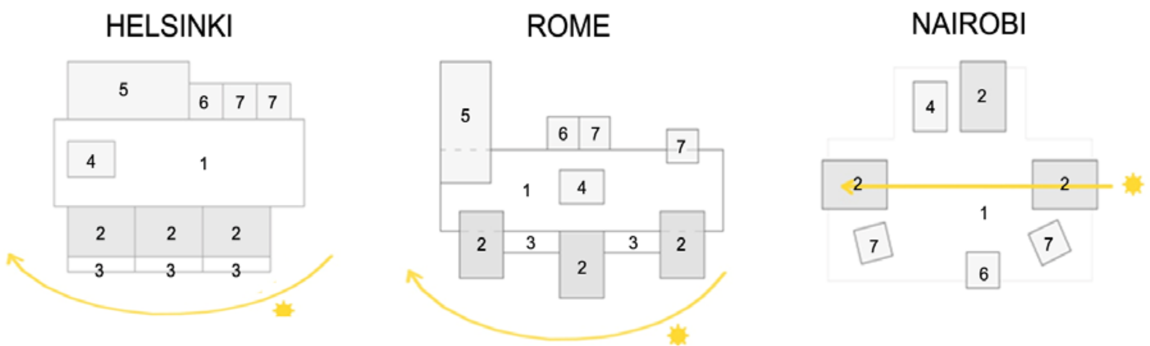

Figure 1 Three possible spaces configurations for the three studied sample schools. Legend: 1 (internal or external) collective space, 2 classrooms also containing bathrooms for children, 3 solar greenhouses that can be also used as porches, 4 bathrooms for faculty and staff, 5 big multifunctional space (canteen / collective play room), 6 technical room, 7 offices.

Technological-constructive performance

Requirements that have greatly influenced the development of the constructive system are:

a) Reversibility of the system for the use in temporary buildings: dry-assembly technology.

b) Application of the same modular and versatile easy-to-build elements in different configurations.

c) Use of low environmental impact components: natural and recyclable materials.

With regard to this last requirement, it is not possible to identify materials or construction systems that have a low environmental impact in so many different climatic zones (culture and economies). In order to preserve the original idea of the research to *"design in different climatic zones with the same constructive system"*, but inevitably at the expense of low environmental impact in some climates, it was decided to use natural materials such as wood. This material has a good relationship between cost and environmental impact in cold climates (e.g. in Finland wood is a traditional building material) and in temperate climates (e.g. in Italy the government is trying to promote the use of wood from environmentally sustainable plantations as building material), while it is less eco-friendly in hot areas such as in Africa. Here the developed constructive system could be realized with local wood or other local natural materials. Being the building single-storey, materials with particularly high structural features are not required. Based on the above considerations, it was decided to use beams and pillars of laminated wood (Gutdeutsch,1996) for the big collective space (not provided in the African application) and cross laminated timber wall- and ceiling-panels (Lehmann, 2012) for the rest of the building (e.g. classrooms, bathrooms and offices, which are designed as prefabricated boxes). The outside wall covering is made of painted wooden slats, while the thermal insulation is in wood wool or pressed cellulose. Structural elements are identical in the different possible design configurations, while the layers of the building envelope (in particular thickness and materials of thermal insulation) change in the different climatic zones in order to improve the energy-environmental performance. Sizing of modular elements (easy movable by one to three not specialized people), construction details and assembly systems (see fig. 2) have been developed in close cooperation with Italian manufacturers of wood components. This collaboration has allowed evaluating feasibility and costs.

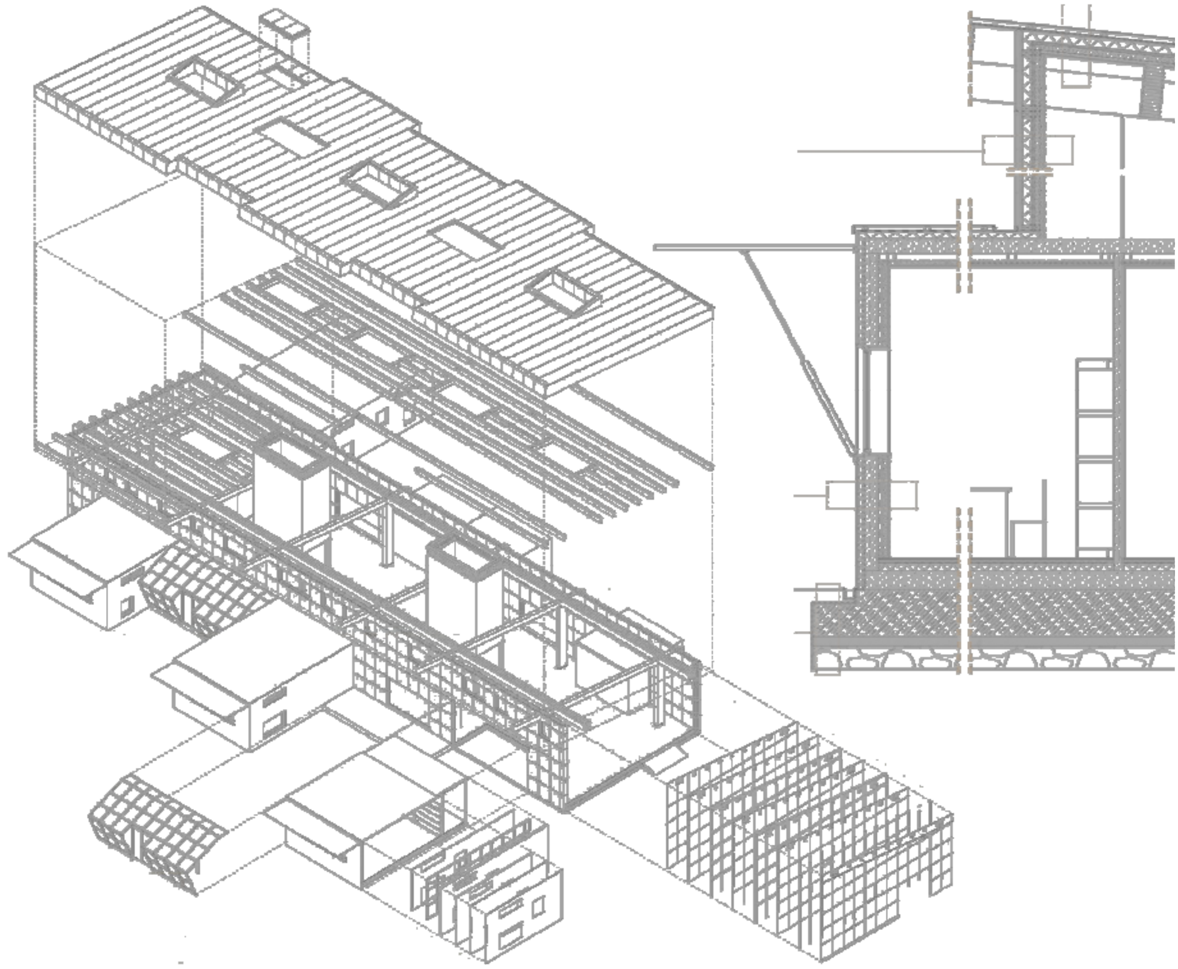

Figure 2 Project proposal for Rome: exploded isometric and detail section of a classroom.

Energy-environmental performance

The achievement of high energy-environmental performance has been the main objective in the development of the construction system and in the design of its possible applications in kindergartens located in different climatic conditions. The most difficult challenge has been to design *one* constructive system and *many* design solutions able to meet requirements sometimes contradictory to each other: 1) design a very flexible system: elements should be as *"neutral"* as possible, in order to work well in any design configuration, 2) application of the constructive system in low energy consumption and high comfort buildings: design and technological solutions should be *"specific"* and calibrated on the basis of different local climate (Ford, 2007) and users needs. The search for balance between "neutral elements" and "specific design solutions" has led to a long “try and test” phase finalized to reach an energy balance optimization understood as result of double simultaneous adaptations: the one dedicated to energy needs based on climate condition and the one dedicated to the environmental comfort for users. So building elements, in particular facades, have been conceived as three layered element: an external cladding, a middle “control” layer (dedicate to modulate thermal and moisture fluxes through the whole building surface) and an inner structure (a mechanically more rigid part of the wall). This design methodology is inspired from the research “The Perfect Wall” carried out by Joseph W. Lstiburek (Lstiburek, 2008).

With the intent to achieve high energy-environmental performance, this research aims to develop not only the elements composing the constructive system, but also the "assembly method" and the relations of these elements. This "assembly method" involves the use of (active and passive) strategies and devices for the improvement of the environmental control. As strategies it means e.g. building orientation towards cardinal points and prevailing winds, surface-to-volume ratio and windows orientation. The devices are e.g. solar screens, high performance building envelopes (e.g. characterized by high thermal transmittance or high thermal inertia), ventilation chimneys, Trombe walls, solar greenhouses, photovoltaic etc.

APPLICATION IN THREE CASE STUDIES AND ENERGY EFFICIENCY VERIFICATION

With the intent to verify the spatial-functional, technological-constructive and energy-environmental performance of the developed constructive system, it has been applied in three case studies located in Helsinki Finland, Rome Italy and Nairobi Kenya.
With regard to the environmental-energy performance, accurate analyses of the local climatic conditions (temperature, rel. humidity, wind speed, direct and diffuse solar radiation etc.) were conducted with the support of the software Meteonorm (fig. 3).

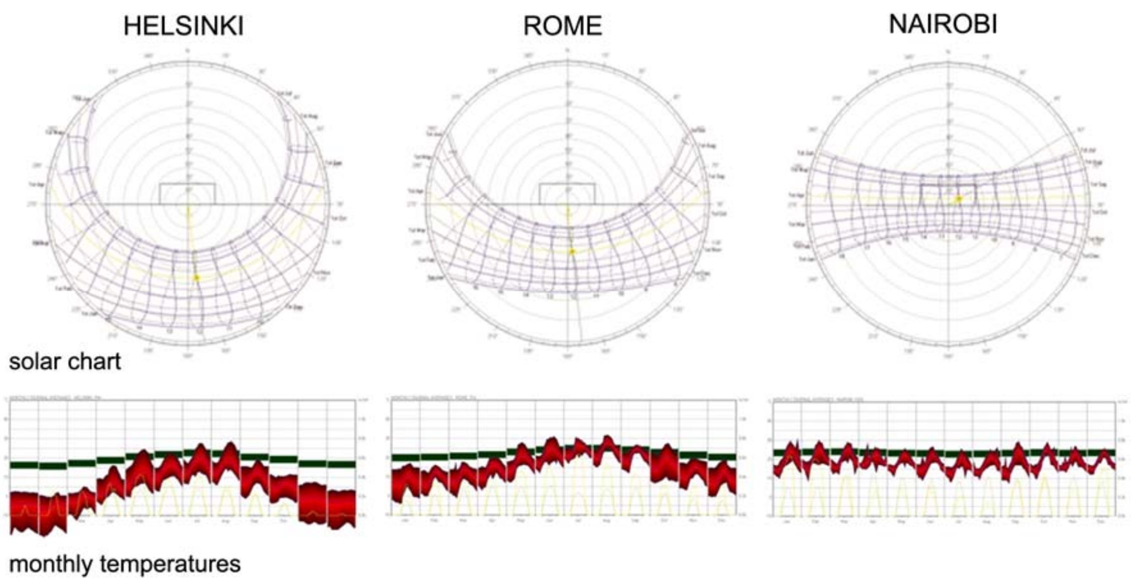

Figure 3 Example of climate data analyses: solar charts and monthly temperatures.

The climate data were the basis for the elaboration of psychometric charts (fig. 4), in which different design strategies and devices (thermal mass, passive solar heating, natural ventilation etc.) are verified in relation to the maximization of “users comfort zone”.

On the basis of this results, in each of the three chosen cities, appropriate strategies and devices have been developed and applied in a design project (fig. 5) that are shortly presented in the following paragraphs.

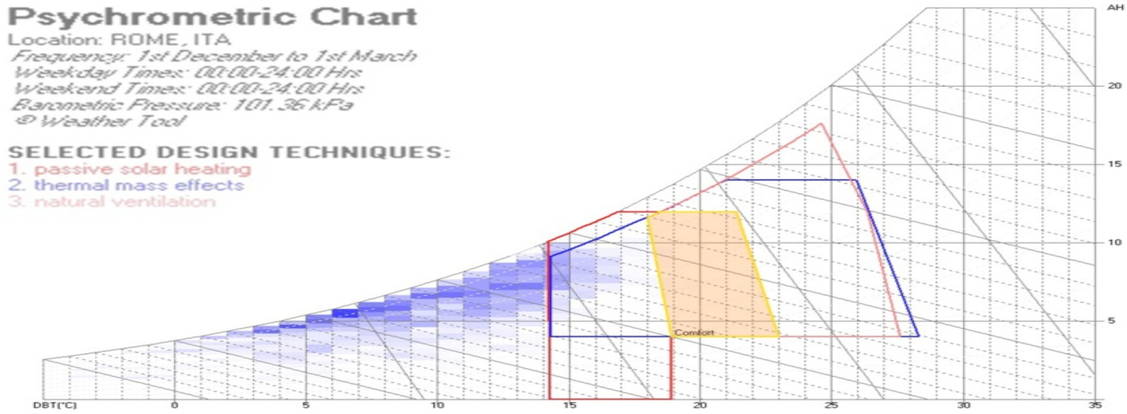

Figure 4 Example of psychometric chart with “design strategy” – Rome.

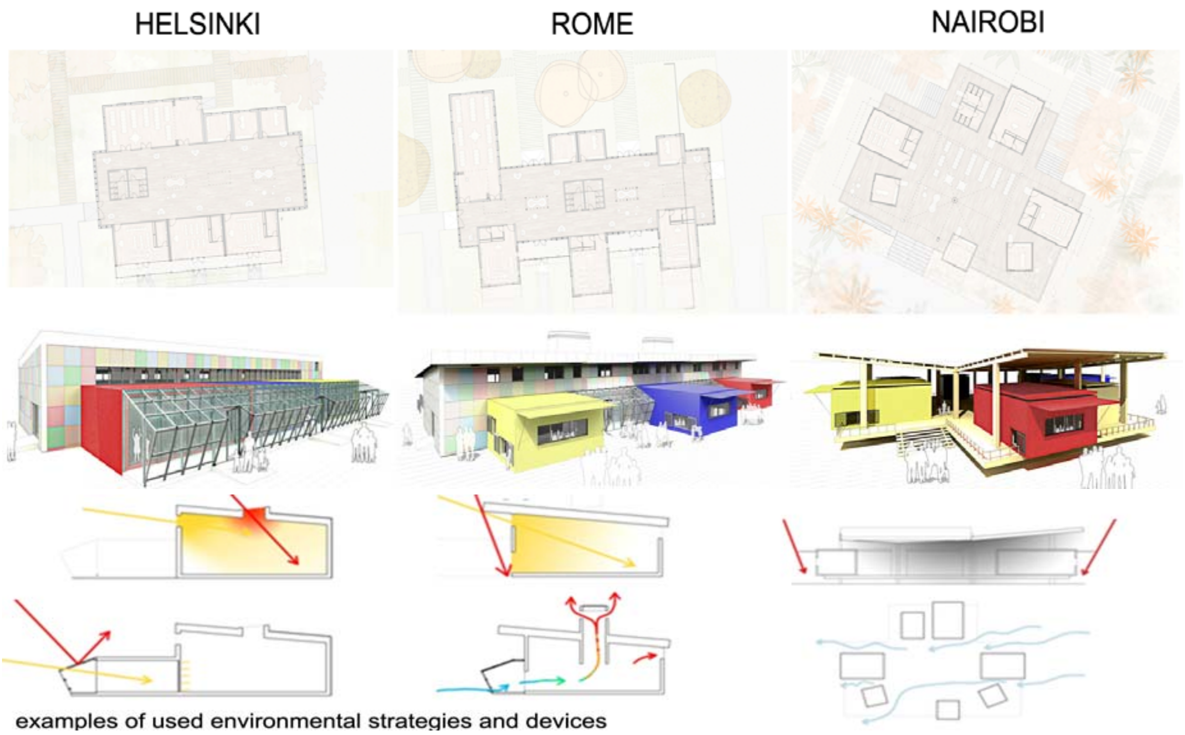

Figure 5 Design application in the three case studies and examples of used environmental strategies and devices.

Helsinki (Cold climate: winter strategies and devices)

Orientation of the building: main axis direction east-west, *S/V* = 0.56 (compact form, low thermal dispersion), *U-value Nord façade*: 0,19 W/m^{2}K (passive building) *Insulation material:* wood wool, *Window to wall ratio Nord façade:* 20% , *Window to wall ratio South façade:* 85%, *Other devices:* maximizing day lighting through windows in the roof and in the south side, efficient solar greenhouses, heating system (see figure 5).

Rome (Temperate climate: winter and summer strategies and devices)

Orientation of the building: main axis direction east-west, *S/V* = 0.63 (articulated form, medium thermal dispersion), *U-value Nord façade*: 0,35 W/m^{2}K (compatible with the Italian regulation) *Insulation material:* wood wool and pressed cellulose, *Window to wall ratio Nord façade: 30%*, *Window to wall ratio South façade:* 50% in winter and 35% in summer, *Other devices:* building envelope characterized by a high thermal mass M_s = 230kg, high thermal inertia Y_{ie} = periodical thermal transmittance = 0,10 W/m^{2}K , windows and solar screens suited to maximize day lighting and solar gains in winter and to minimize them in the summer, solar greenhouses in winter / porches in summer, passive cooling through stack and cross ventilation optimized for the specific climatic conditions, evaporative cooling, heating and cooling system (see figure 5) (Beckera et al., 2007; Filippin et al, 2007).

Nairobi (Hot climate: summer strategies and devices)

Orientation of the building: square plan around a outdoor covered collective space, *S/V* = 1.12 (permeable form), *U-value façades*: no thermal insulation, only acoustic insulation exclusively for classrooms (pressed cellulose or local materials), *Window to wall ratio:* ca. 35%, different for different orientation. *Other devices:* building raised above the ground separated volumes and raised roofs to maximize natural cross and stack ventilation, high heat loss common areas outside under a large cover that shields even the buildings below, no heating and cooling system (see figure 5).

The energy efficiency of these design choices has been quantified through a set of affordable design tools like: thermo K8 (a common practice used software for the analysis of thermal performance of multi-layered single constructive elements), Heat (to proof thermal bridges) and Autodesk Ecotect (a dynamic simulation model managing each thermal zone in an inter-zonal calculation process to evaluate the comfort level and to calculate the energy demand during the time). The energy performance is quantified under static and dynamic conditions and is verified (if possible) in relation to the regulation of the three different chosen countries (particularly Finland and Italy).

The analyzed parameters are:

- For the single constructive elements (particularly façades): U-value, superficial mass, thermal lag , decrement factor, periodical thermal transmittance, vapor diffusion resistance and air permeance (based on recursive-steady state calculation Glaser method).
- For the single rooms. Classrooms: thermal hydrometrical comfort - PMV, acoustic comfort, day lighting and lighting comfort on the floor and on the work level. Greenhouses: annual passive solar gain.
- For the whole building: annual energy demand for heating, cooling and lighting, annual passive solar gain in cold climate and in temperate climate in winter (see figure 6).

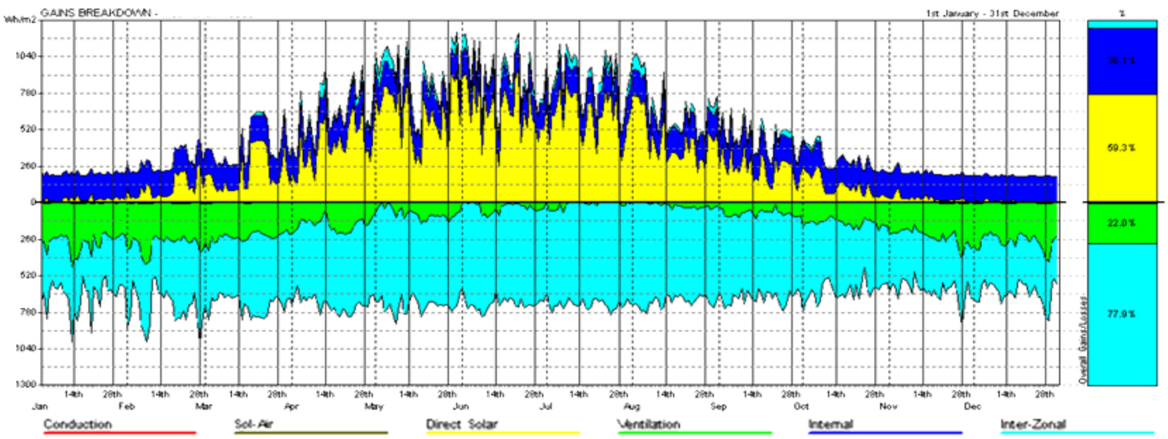

Figure 6 Annual passive solar gain - case study Helsinki.

From an energy simulation point of view the results consider thermal comfort range of 5°C temperature swing an 10% relative air humidity as a driver for air-mass-envelope exchange of sensible and latent heat according the idea of minimize, or exclude the role of HVAC facilities during three seasonal condition (spring autumn and winter). Even if the results of building simulations can be simplified it takes in account a sensible reduction in monthly degree day for heating and cooling according the energy saving methods in the three climate conditions. This acts as a whole building design considering alternative design solutions in a didactic perspective for students as a possible experimental platform to better improving cost, comfort and energy efficiency standards.

Simulations were not carried out after the project end but as very important part of a optimization recursive design process. Indeed, this "open-solution model generator" approach typical for the used software (in particular Ecotect) is a simple design methodology for the designer (e.g. architects) to control the different results and influences of a particular design solution (e.g. building shape or assembly method), air change rate, occupation, internal loads etc. to internal comfort level, energy demand and energy balance of the entire building. With the intent to minimize the use of active systems, passive solar analyses (fig. 6) are one of the most interesting intermediate results of this research for the appropriate use of devices like greenhouses, evaporative cooling etc.

All the simulations carried out in the three case studies have shown a high level of environmental comfort and an extremely small internal energy demand for heating, cooling and lighting in relation to the climatic zone. Kindergartens designed in Helsinki and Rome achieve the standard “near to zero energy building” (with the use of passive devices and active systems like photovoltaic and solar collectors). Moreover, in all three buildings PMV has values between -1 and +1 even in periods with extreme climatic conditions (Helsinki in winter or Nairobi in summer).

CONCLUSION

In conclusion, tests (design application, static and dynamic simulation) conducted in this research have shown that the developed reversible constructive system (applicable in temporary schools) combines good spatial-functional and technological-constructive qualities with a high level of indoor comfort and a low energy consumption for heating, cooling and lighting. Moreover, the system resulted extremely efficient also in very different climatic conditions, thanks to its easy adaptability to different configurations and strategies.

This work was born in a school of architecture as a graduate thesis presenting an environmental research scenario for locations with peculiar climate and performance needs based on the final better judgment from the design team. From an educational operative perspective the work of comparison between different performance responses is an open-mind attitude to stimulate the research in sustainable construction methods.

The architectures' primary role is guaranteed as the method gets a lot of dedicated input information to lead in the design phase. Each information can have a particular importance in processing the ideas from a sketch or from a detailed commission request, (for example from a local government program).

The collaborative role of building physics became not abstract or simply theory, but is addressed to be an useful cooperation design technique.

ABSTRACT HEADING

This applied research is to design a buildable high energy efficiency modular prototype of urban housing, able to overcome the sustainable weaknesses of housing construction in centre-south of Chile, present in all economic and social sectors. This deficiency is originated by lack of adaptability of the typical shapes and construction to environmental requirements of the local climate, resulting in serious inefficiencies in their energy performance and comfort. A building system was developed by a multidisciplinary research team, with support from representatives of the local builders and real estate market, generating highly energy-efficient homes based on the integrated design approach. The prototype allows covering diverse residential needs, considering both the build surface and the number of habitable rooms, creating scalability in time and extension. The system, called "CASA+" (Spanish acronym of "House plus", due it offers higher diversity and comfort than current designs), can arrange different settlements, to create diverse urban densities and efficient use of sunlight.

BACKGROUND AND OBJECTIVES

Residential buildings in centre-south Chile have made consistent progress in the recent decades. Most of this growth is based on detached houses, executed in repetitive groups of a reduced size, of up to 60m2, which subsequently increases spontaneously forming variable clusters with few facilities and a lack of urban cohesion. So far, the priority in Latin American's urban development has been to face the demand for basic housing, relegating, when not ignoring, the environmental problems, which has meant building inefficient homes with high energy demands, particularly significant in climates with a strong seasonal variability. In the Centre-South Chile there are specific studies that put these demands in a range between a minimum of about 110Kwh/m2 for detached houses with two floors, and a maximum of 192Kwh/m2 per year. In the simulations performed as part of the research project MEL CONICYT 81100003 (2011-2012) "Integrated Design for Energy Efficient Housing Reconstruction", the average heating energy demand of a detached house in the study area has been calculated as 143kwh/m2. This demand is fulfilled with burning combustion systems, especially in the lower class areas, combining poor fuel quality (non-certified wet wood) with low efficient equipments, resulting in poor indoor thermal conditions (with an inner average temperature of 16°C) and poor indoor air quality as a result of inadequate combustion. In the current context of strong growth of housing construction after the earthquake of 2010, and given the high price of conventional energy, reducing the energy demand has become a priority within the strategic objectives of the country's development.

The project starts from the realization of the limitations of the previous experiences, and proposes a flexible system that enables the development of energy-efficient homes with multiple possibilities for grouping and growth under different climatic and socioeconomic levels for different areas. It is solved by a modular, replicable and high customizability construction system, that increase the quick construction after an earthquake, minimizes the costs and guarantees the constructive quality of an industrial process, inside the long tradition of this tipe of architecture (Prouvé, Koening, Lods, Ehrenkrantz). The development of the system is now in the penultimate stage of the project.The earlier stages consisted of analyzing the climate and constructive problems of the study area and its architectural background. At the current stage, the foundation for the design of CASA+ has been laid (the detailed implementation plan that defines the construction of a real-scale prototype is yet to be developed). The work methodology has been the Integrated Design Process, which combines multidisciplinary participation with different points of view with a working model that predefines the goals to be achieved (qualitative and quantitative), developed in successive steps of complexity.

The specific goals have been defined in architectural aspects (minimal surfaces, grouping and integration ability), urban aspects (minimum density), economic aspects (cost range) and construction fields (modular systems and construction according to the local industry); as well as achievable goals for energy efficiency, as a minimum verifiable saving result was set to not less than 55% (category A in energy efficiency) with respect to a traditional house taken as reference.

The aim is to rethink the characteristics of traditional Chilean housing, consisting of a two floors house typology, with a length-width ratio of 2 to 1 and gabled roof, usually arranged isolated or paired, and with surfaces ranging from 36m2 (low income housing) to 90m2. In the middle or lower-middle class subsidized housing sector, the surface and number of bedrooms is very similar to the prototype of 60m2. (Fig.1). Extensions in upper modules, with a third floor or living space under the roof, can raise the prototype's surface up to 90m2 with four habitable rooms. It is also possible to extend the modulation by the sides, increasing the surface area due to the modular nature of the proposal. The multiplicity of grouping possibilities from the same unit can generate many different neighborhoods and densities, along with material and surface characteristics of housing and the plot's size without sacrificing the basic qualities of spatial quality and energy efficiency of basic housing (Fig.2).

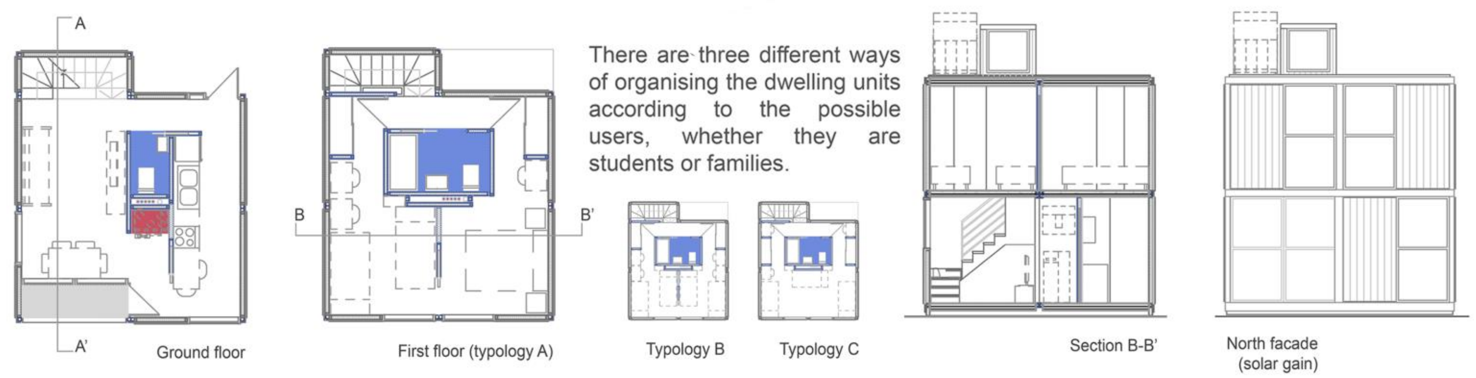

Figure 1. Architectural definition of the 60m2 prototype.

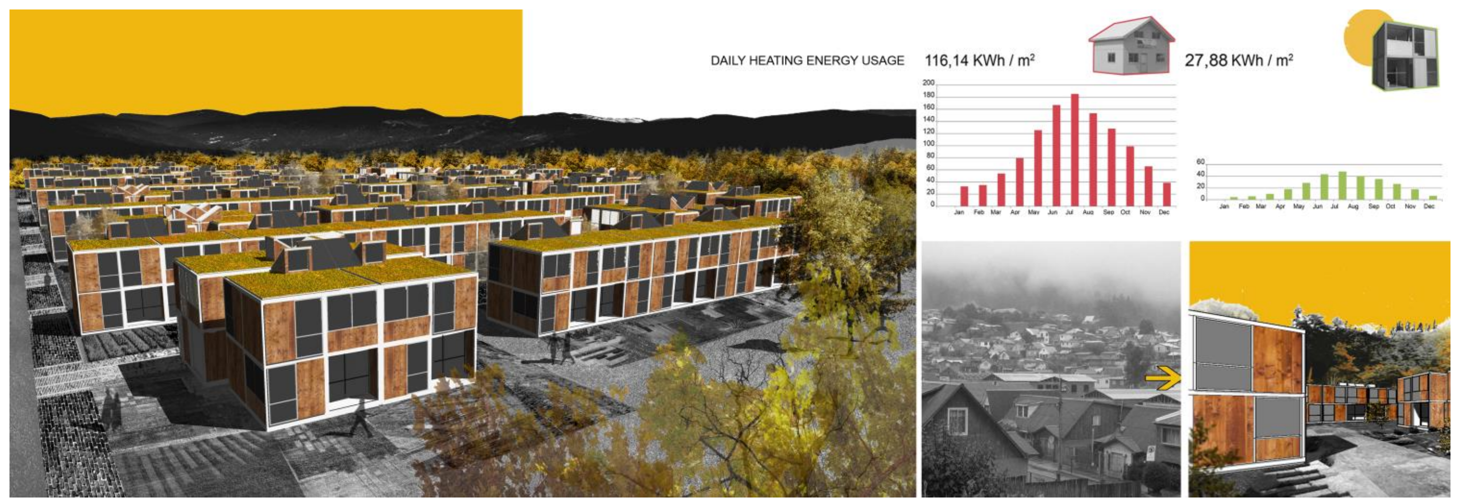

Figure 2. Example of neighborhood using the prototype. It changes the traditional system of grouping houses and improves the energy efficiency as well.

DESIGN STRATEGIES

CASA+ should be understood as a system design, a set of architectural and constructive elements that with different possibilities for clustering on each scale result in diverse architectural and urban solutions having in common a significant improvement in energy efficiency with respect to a conventional home of the same size. It combines a number of solutions adapted to different architectural scales, considering different environmental stresses taken from the detailed climatic analysis carried out during the development of the MEL research.

In the geographical scope of the study, the analyses show needs for energy input (heating) in winter, sun protection and natural ventilation in summer (no need for cooling) and a need for reducing humidity throughout the year. The bioclimatic diagrams for Concepcion's area shows that there are long periods of the year (winter, spring and fall) where the passive solar contribution would be sufficient to reach the comfort zone, requiring only some heating input at some specific periods (Fig.3).

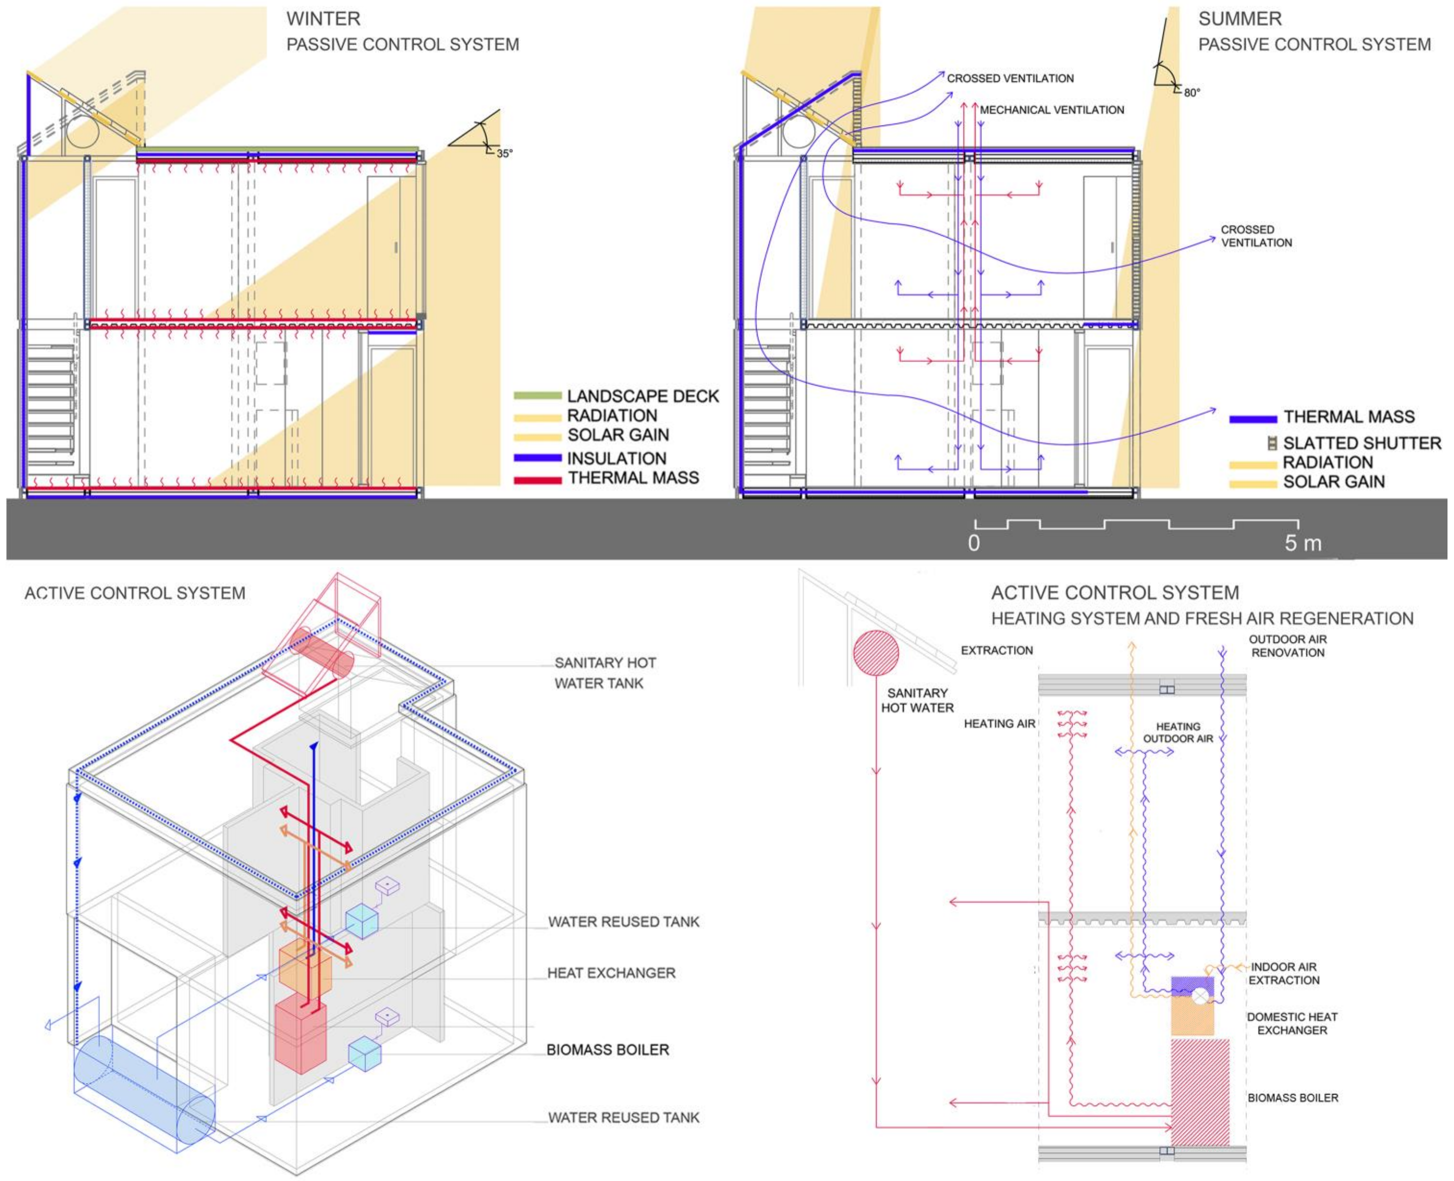

Figure 3. Passive and active climatic control systems of the prototype.

The following design strategies to consider in the prototype depending on the environmental requirements defined in the climate diagrams of reference:

- The strategies to reduce the thermal losses, as the decrease of the envelope area by compact units with a small form factor and by aggregations of more units (detached homes, attached or block). To do this, CASA + adopts a structure based on cubic forms, thus reducing significantly the form factor, with a relationship surface/volume of 0.75 (the area by reference is the sphere, 0.60). When compared to a traditional house with the same area, usually prismatic, CASA+ reduces the exposed surface by 20%. The prefabricated panel system with inner insulation, implying a U factor of 0.37 W/m2K and 0.31 W/m2K for walls floors and roofs. The windows, using double glazing with low emissivity, are a U value of 2.41 W/m2K, and the improvement of the transmission coefficient in joinery, using systems of thermal break.

- The strategies to increase the profits are the well-orientation house and windows for solar gains (CASA+ orientates one main facade to north +/- 45°, where all living spaces are placed). The correct dimensioning of windows in the north facade between 60% to 75% of the facade's surface, which represents between 20 and 30% of the floor surface, as recommended by simulation programs. Also the prototype improves a heating system's of high efficiency, using a combustion system of a biomass boiler of pellets. Finally, thermal inertia is incorporated in interior walls and decks.

- The strategies to improve the ventilation and infiltration rates, is an important point due to the high relative humidity rate in the study area (around 70%). CASA+ introduces a system of natural cross-ventilation through the opening of windows on the roof, and introduces enthalpy exchangers with double function, forced ventilation and heat recovery. A suitable infiltration rate to be achieved is 1ach, which implies a more airtight construction (manageable by the local industry), through proper sealing joints between panels and facade cover, and between them and the window frames.

- The strategies to reduce the solar insulation in summer (although extreme heat conditions are not climatically significant in the study area) in highly exposed north facades during the summer (even more with the high amount of window's surface), are the use of setbacks on facades to generate shadow.

ARCHITECTURAL DESIGN AND CONSTRUCTION SYSTEM

The building systems used in the traditional construction are variable, but the most common consists of a first story made of masonry confined in a concrete structure and a second story with a gabled roof made of timber framework with enclosures made of wood panels. The thermal behavior of traditional housing is a consequence of the construction system, which follows the established legal rules. The location and placement of the housing plots follows an economic criterion (filling all the available space) rather than a rational study of local climatic factors (orientation, sunlight, obstruction).

The prototype attends, however, to a global concept of sustainability, which involves not only the improvement of the comfort conditions (compared to traditional housing) through improved building systems, but also through a correct formalization and orientation of the dwellings in the urban context. The improvement of the form factor intervene in this point, as it implies a better relationship between volume and surface area, and is complemented with a modular construction system, based on a sandwich panel SIP, with a modulation of 2.45 m x 1.225 m, which can be placed either vertically or horizontally. They conform cubic units to the addition of a structural framework, establish the basic unit in modules of 2.67m x 2.67m. The plan of CASA+ is arranged with the junction of 4 units, generating a square of 5.34 m. side and 28.5 m2 of floor area. The basic house, with two levels, is then defined by an area of 57m2, to which the staircase module is added. This element is conformed as one piece attached to the cubic structure in the opaque facade, generating a total area of 60m2 and 53.5 m2 of floor area.

As a result of the contact with companies of the construction sector in the study region, it has been decided to use a mixed construction system that combines elements that may either be manufactured in a workshop or industrialized (such as cladding panels and decks), with uncomplicated assembly work (Fig.4). The materiality of the finishes, enclosure systems and decks can be easily exchanged, leading to multiple aesthetic choices. The constructive system consists of a structural system, an enclosure and a facilities system. The facades are solved by a wood sandwich SIP panel with EPS insulation 100mm thick. These elements may or may not be coated on their inner sides, while the outer face comprises a waterproof treatment and may be coated with a waterproof and breathable membrane. The finish is a ventilated facade system of lightweight concrete 10mm thick. The outer panels are directly fixed to the structure, formed by a framework of beams and pillars that define a cubic cage, which can be done in steel, solid or laminated wood, and can come directly manufactured or prepared to be assembled on site using screws and pins. Diagonal bracing ensure vertical stability, while the horizontal stability is stiffened by the slabs. The foundation can be done on site with ditches, or come prefabricated as concrete blocks. The slabs, in the basic proposal, are made of concrete with steel decking 0.75mm thick that can be performed on site or come prefabricated from the workshop. However, since in some climatic regions studied, the difference day-night temperature is not very significant, they could be replaced by lighter elements such as the same SIP sandwich panels used in the facades but with a higher thickness (150mm.). The roof is defined by the same deck, incorporating a landscape deck. The staircase is considered as a prefabricated separate element.

The bathroom and kitchen facilities can be performed either in a traditional way or come prefabricated from the workshop. The lower floor's wet unit, where kitchen and toilet are grouped, and where an air conditioning indoor unit could be placed, can be done industrially, including furnishings and appliances, and then be assembled in the working place. The climate control system is designed to support a unit of biomass considered carbon neutral, located at the center of the house. Given the need for ventilation due to the humid climate (1 ach), the climate control system is supported by a system of heat recovery located in the forced renewal unit. Natural cross ventilation is established between the lower floors and the skylight located over the stairway. Supports for solar or photovoltaic energy are installed on the flat roof.

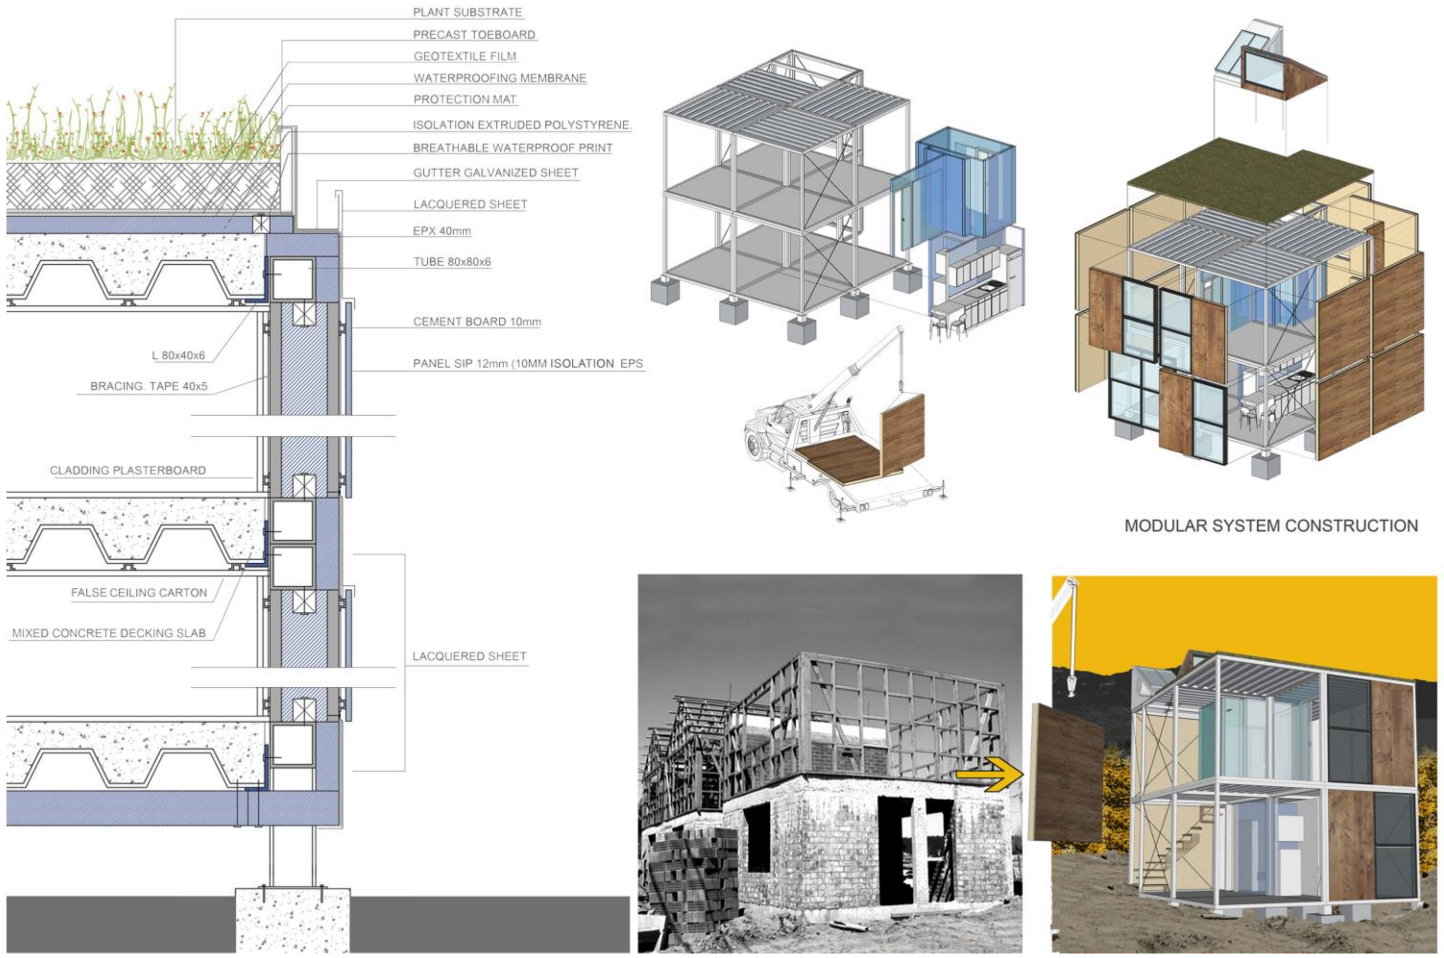

Figure 4. Construction modular system and the difference with the traditional construction system.

RESULTS AND CONCLUSIONS

About the architectural proposal for the CASA+ housing model previously described (2 floors and 60m2); simulations were performed with specific software. All simulations were performed with a north orientation of the main facade. In all the studied cases, sharp declines in energy demand were obtained when comparing data between materiality referred to the Thermal Regulation and the proposals. Several starting decisions for the architectural design, and the choice of materials, have been predicted from previous investigations, such as increased insulation of the envelope to suitable U values, the use of inner thermal inertia, or the dimensioning of the windows in approximately 20% of the floor surface (Fig.5). From the results obtained in the simulations, the following conclusions can be drawn:

- The CASA+ prototype, simply by being architecturally designed according to the climatic conditions, obtains, using an envelope according to the Thermal Regulation for a comfort range between 18°C and 27°C, an energy demand of 115-100kWh/m2, lower than homes built today in Chile in the area on the research, which ratio ranges from 190kWh/m2 to 143kWh/m2, according to data provided from previous research.

- The CASA+ prototype developed with an improved thermal envelope in relation to Thermal Regulations, shows a decrease in energy demand of 70-75%, and fits into the category A of energy efficiency as it shows savings exceeding 55% over the reference building according to TR. This improvement increases up to 75-80% in the case of semi-detached houses, with a common dividing wall, and 80-85 % in the case of terraced houses matched by two sides. Improving energy efficiency in detached and semi-detached houses is between 20-22% in the case of semi-detached houses and between 30-32 % for terraced housing. The values in the lower ranges, between 47 and 16 kWh/m2 are values already adjusted to acceptable quality standards in developed countries.

Figure 5. Energy saving simulations.

Another quality of the prototype is to achieve these standards with a sufficiently tight economic investment in cost-benefit ratio. The budget studies show that the construction of CASA +, considering the plot, represents an impact of 57USD/m2 , which fits into the average cost, that is at the 65USD/m2 . Major savings could be achieved by improving the execution times at the workplace, increasing prefabrication, which could lead to improvements in finished or increscent of the floor area.

The first CASA+ prototype is currently in the pre-project implementation phase. The interest of the property market on the proposal, leaves the door open to a new phase in which, if it is possible to combine synergies and attract the adequate funding, the completion of a construction project. Its development would be made in UBB to assess the complexity of construction, cost and assay, and above all, to make the energy monitoring over a prolonged period of time, so that the feasibility of the proposed scale can be demonstrated. The research methodology allows to be extended to other climates of the region and other Latin American socio-economic realities, with a previous study of local peculiarities, both in terms of climate and the constructive development. The system, currently limited to detached or grouped house, could be developed using the same methodology for high-rise housing. The private sector participation in the development of the system is considered crucial by being involved in the technological development and financial feasibility, as well as the legislature, by facilitating the exchange of improving energy efficiency by equivalent improvement in the construction and architectural quality of the middle and lower class's homes.
